L

LABELS. Made-up chemicals are usually well enough labelled by the manufacturer for the label to remain readable throughout the life of the contents. But trouble arises with bottles containing stock solutions. These are handled more than most bottles—often with wet hands—and the inevitable dribbles of solution soon discolour and loosen ordinary gummed labels.

The two essentials for such labels are that they should be clear and be proofed against wet solutions so that they will stay clear. The label should be boldly printed on white paper in ordinary draughtsman's waterproof indian ink. It can then be made solution-proof, in one of two ways.

For a temporary job, the label should be held in place with transparent cellulose adhesive tape. The tape should cover the whole label and overlap generously on to the bottle all round so that dribbles of solution cannot get at the label. This method is useful for labels that carry the date of making up; they are easy to strip off and renew.

Permanent labels are best attached with a fairly thick solution of celluloid in amyl acetate—made by shredding old film, cleaned of its emulsion, into the solvent and leaving it for a day or two. The bottle should be polished clean and dry, and then given a coat of the celluloid varnish. When this coat is dry, the back of the label is brushed with the varnish and pressed on to the bottle. After half an hour, the front of the label and the side of the bottle for half an inch around are coated with the varnish. This makes a permanent label which will withstand handling, solutions, and washing in cold water. It will stand up to hot water long enough to allow the bottle to be washed out.

Perspex dissolved in chloroform or ethyl acetate makes an even harder and more water repellant coating.

Another temporary label can be made by writing on the glass with one of the special pencils sold for the purpose, and covering the letters with cellulose tape. Glass writing inks are also available from laboratory suppliers in various colours (including white for dark bottles). They will not wash off and can be removed only by hard scrubbing. Another alternative is the special self-adhesive tape with a white, matt "write-on" surface. The title is printed on the matt side and the section of tape simply pressed on to the bottle.

But no matter which system is used, the solution should be labelled right away to avoid mistakes. Relying on memory is bound to lead to errors.

It is a good plan to mark bottles with labels cut to a distinctive shape—e.g., round for negative developer, triangular for fixer, long and narrow for paper developer. As soon as the shapes become familiar, it is no longer necessary to read the label. This can be useful when working only by safelight.

Another valuable aid to quick and certain recognition is to store the various processing solutions in bottles of different shapes and sizes.

This may produce an untidy array of bottles on the shelf, but it makes the solutions so much easier to recognize by sight, and it is the only way of recognizing them by touch in the dark.

Where small objects such as nails, screws, etc., are kept in boxes, place a sample of each kind on a sheet of bromide paper under the enlarger and make a silhouette print. This makes a label that is easier to see at a glance than a printed description. F.P.

LAINER, ALEXANDER, 1858–1923. Austrian chemist, professor at Salzburg and Vienna. Recommended in 1889 (independently of M. Andresen) the acid fixing bath for the removal of fog. Worked on platinum prints and discovered in 1896 the Lainer effect (acceleration of developer action by potassium iodide). Established (1900) in Vienna a dry plate and paper factory (later Herlango).

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

LAMBERT. Unit of brightness applied to the measurement of the luminosity of illuminated surfaces and of incandescent bodies. One lambert is equal to a rate of light emission or reflection of one lumen per square centimetre—i.e., 10,000 lumens per square metre.

In scientific work the brightness of a surface is expressed by a measure of the light emitted or reflected by it, and termed its luminance in terms of its luminous intensity per unit area (candles per square inch).

See also: *Light units.*

LAMP. Artificial light source, usually electrically powered. The lamp is the source itself (e.g. the light bulb), and is used in various lighting units such as reflectors or spot lamps for lighting up the photographic subject, or incorporated in an optical system for projection etc.

Photographic Lighting. Most lamps for lighting the subject are of the incandescent tungsten filament type. They range in power from 100 watts up to 10,000 watts, and may be used in lamp reflectors or lamp units for flood lighting, spot lighting, etc. Special miniature spot lamps are employed in photomicrography and other scientific fields.

Other lamp types for lighting the subject include fluorescent and vapour discharge lamps. With some of these the output of invisible radiation (e.g. ultra-violet rays) is used for special photographic techniques.

Discontinuous lamps—flash bulbs, electronic flash and spark sources—are employed both in normal photography and in high speed work. Carbon arcs used to be popular for high intensity lighting, but are nowadays nearly completely displaced by high-power incandescent filament lamps.

Projection. Most projector lamps, especially for still and narrow-gauge cine projectors, are again incandescent filament lamps. High-power motion picture projectors may use carbon arcs or—in modern units—concentrated gas arcs.

For highest light efficiency, lamps of this kind frequently use the nearest approach to a point source with a suitably designed condenser or other optical system.

Small size transparency viewers employ either normal filament lamps or—in the pocket type viewer—battery-powered miniature lamps. Large-size display cabinets for transparencies frequently use fluorescent tubes of selected colour quality as the light source.

Printing and Enlarging. Lamps in contact printers and printing boxes are nearly always groups of filament lamps. Small amateur printers may use a single 15 watt lamp; large size printing boxes may take up to a dozen lamps of 60 or more watts each.

Enlarger lamps are mostly filament lamps of 75 to 250 watts; some enlargers use over-run projection lamps with a suitable optical system. Special forms of discharge lamps (cold cathode lighting) sometimes provide a uniform area of diffused light.

Printers and enlargers for photo-mechanical reproduction may work with mercury vapour or other discharge lamps. These yield a high intensity of ultra-violet radiation to which certain graphic arts and copying materials (e.g. pre-sensitized litho plates or dyeline papers) are specially sensitive.

Darkroom Illumination. While conventional darkroom lamps use low power filament bulbs (mostly 25 to 40 watts), the spectral characteristics of sodium vapour lamps and of electroluminescent panels have been employed to provide a light safe for certain types of sensitive material.

LAMP CAPS AND FITTINGS

When ordering or replacing lamps for use in photographic lighting or apparatus, the photographer needs to know certain details of construction to avoid mistakes.

There are British Standard Specifications dealing with the basic types of electric lamp. Most lamp manufacturers list these standard types under various trade code descriptions, and most also manufacture non-standardized types for special purposes.

When ordering ordinary tungsten filament lamps for any purpose, the minimum essential data to be given are: voltage, watts consumption, type of glass envelope—i.e., clear, frosted or opal—and type of cap.

When ordering other types—e.g., projector bulbs, studio spotlights, fluorescent and vapour discharge lamps, and flash bulbs and tubes—it may be necessary to state further particulars—e.g., A.C. or D.C. supply, and the maker's code description.

Both electric incandescent and flash bulbs are fitted with caps that allow them to be secured in a lampholder and connected to the electricity supply. These caps differ in both design and size. The following descriptions cover the lamp caps most used in photography, but there are many others which are used less often for specialized applications.

In addition to the different types of cap connexions listed below, various adaptors are made to enable one type of cap to be used in a socket of different type.

Bayonet Caps. The bayonet type of cap is pushed straight into the socket and turned clockwise to secure it, two studs on the body

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

LAMP CAPS. A, giant Edison screw (G.E.S.). B, Edison screw (E.S.). C, double bayonet cap (B.C.). D, small centre contact bayonet cap (S.C.C.). E, three-pin bayonet cap. F, mogul prefocus. G, medium prefocus (P.F.). H, double contact prefocus (motor car headlight type). I, two pin. J, double contact prefocus with slotted flange. K, bipost. L, 4-pin base.

of the cap engaging with shaped slots in the socket.

There are two normal double contact sizes—the large double contact bayonet cap (B.C.) and a smaller double contact version (S.B.C.). The filament in B.C. and S.B.C. lamps is connected to two insulated contacts on the base.

Single contact lamps have a single central contact and the circuit is completed through the wall of the cap itself. There are single centre contact versions of the large cap (C.C.) and the small (S.C.C.). There is also a miniature centre contact cap (M.C.C.).

The B.C. is used in Great Britain (but not in America) for domestic and some photographic lamps of relatively low consumption (up to 150 watts). The smaller type of cap is used in flash bulbs, motor car lamps and in instrument lighting circuits. The miniature cap is used on pilot and indicator lamps.

In the U.S.A. the S.B.C. and S.C.C. caps are also known as double contact bayonet candelabra (D.C. Bay.) and single contact bayonet candelabra (S.C. Bay.) respectively.

Screw Caps. There are four common types of screw cap, the miniature Edison screw (M.E.S.), the small Edison screw (S.E.S.), the Edison screw (E.S.),and Goliath Edison screw (G.E.S.). The M.E.S. cap is used on flashlamp bulbs, pilot and indicator lights; the S.E.S. on miners' handlamp bulbs; the E.S. cap for all domestic lamps in America, for large flash bulbs and for various lamps of the order of 200 watts in Great Britain, and the G.E.S. cap for lamps of up to 1,500 watts. In addition, a very small cap is used for flash unit test lights.

American equivalents of S.E.S., E.S. and G.E.S. caps are candelabra (Cand.), medium screw (Med.) and Mogul (Mog.) respectively.

Prefocus Caps. Where the filament of the lamp must always be at a fixed distance and position in relation to the base of the support (as in projection lamps) the bulb is fitted with a special type of bayonet cap known as a prefocus cap. There are several types of prefocus cap varying in the method of engaging the contacts and positioning the filament. Three of the caps are used in photographic projectors.

In the first and most usual type there is a single centre contact and the lamp is held in the socket by a pair of flanged projections which engage with corresponding slots in the socket and fix the height of the filament in relation to the base. There are two sizes of prefocus cap of this type, the large prefocus and the medium prefocus.

American designations are Mogul prefocus (Mg. Pf.) and medium prefocus (Md. Pf.).

A second type with double or single contacts and smaller than the above, has a circular locating flange or disc with a single cut away portion which engages with a projecting key in the lamp socket. This type is principally used in motor car headlamps.

The third and smallest prefocus cap is surrounded by a circular flange in which there are three elongated tapering holes; these lock with a bayonet action over three corresponding studs on the face of the socket. This type also has a double or single contact cap (D.C. Pref. and S.C. Pref. respectively in America) and is mostly used in some sound projector exciter lamps.

A modern projector lamp fitting which also locates the filament accurately is the four-pin valve base. This is pushed straight into the corresponding socket. The pins are 1 mm. thick and spaced 15/32 inch or 12.5 mm. apart in a square. The lamp carries a keyed central locating peg which ensures that the filament is corrrectly orientated and that the right pins go into the right sockets. (Only two of the pins carry the current.)

Bipost Fitting. A special type of two-pin cap is used for heavy current lamps in film studio work. These caps, of which there are two common sizes, have contacts formed by two metal posts which are continued inside the lamp as the filament supports. Lamps of this type will carry currents up to 10 kW.

Special Caps. In addition to the above types of cap, there are a number of special fittings used on lamps which have a more limited application in photography.

There are several types of fitting for double

Bi-pin	Double contact			G.24	35 / 23	Fluorescent tubes. Dimensions refer to barrel diameter. Pin spacing = 13 mm.

ended tubular filament lamps—some have an insulated centre contact cap at each end, others have plain metal caps which also form the contacts. A third type of "straight light" tubular lamp fitting consists of metal posts projecting from the back of the tube 38 mm. from each end. This arrangement is adopted so that when the tube is in position in the appropriate type of socket, the contacts and sockets cannot be seen from the front.

Tubular fluorescent lamps are made with two different types of end fitting, Bi-pin (up to 4 feet) and B.C. (8 feet).

Pear-shaped fluorescent and vapour discharge lamps have a three-pin bayonet cap which prevents them from being accidentally plugged into an ordinary tungsten lamp holder. This is necessary because fluorescent lamps must be connected to the supply through a choke; if a vapour discharge lamp could be plugged into an ordinary supply point it would short circuit the supply and almost certainly destroy the tube. Sodium vapour discharge lamps are fitted with ceramic bayonet caps.

Flash bulb caps may be either of the S.C.C. bayonet type (in the smaller sizes) or E.S. type (larger sizes). Modern miniature flash bulbs often carry no cap at all, contact being made directly with the two wires entering the glass.

Electronic flash tubes have caps corresponding to radio valves—e.g., 4-pin, Octal or UX—or in some cases the tube may be supplied with soldering tags only.

Lamp Socket Adaptors. The lamp socket is normally part of the apparatus in which the lamp is used, and there are naturally sockets corresponding to all the types of lamp cap described above. As a general rule any lamp

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

BULB SHAPES. Approximately 1/6 natural size. A, class E projector lamp (for use with epidiascopes and spotlights). B, wide tube class AI projector lamp (for use in lantern slide and similar projectors). C, narrow tube class AI projector lamp (for cine and miniature projectors). D, floodlamp. E, high power studio lamp. F, household lamp. G, integral reflector photoflood. H, integral reflector projection lamp. The blown out bulb shape acts as a reflector and is internally silvered.

plugged into a particular socket should have a cap that corresponds with it, and the differences in shape and size do in fact ensure this. However, there are adaptors which enable one type of lamp cap to be plugged into another type of socket. Such adaptors are always of a type that will permit a lamp to be plugged into a socket designed for one of higher consumption, never the other way round. (If a low power socket were adapted to take a high power lamp, the fuse would blow when the lamp was switched on.)

The only exception to this rule applies to adaptors for flash bulbs. In this case there is no objection to the use of a large bulb in a small socket, and suitable adaptors are available for making all sizes of flash bulb and socket completely interchangeable.

The most useful lamp socket adaptors are the G.E.S. to E.S., the G.E.S. to B.C., the E.S. to B.C. and the B.C. to E.S. In addition, for flash bulbs, there are E.S. to S.C.C. and S.C.C. to E.S., as well as capless to S.C.C.

Lamp Shapes. The shape of the glass envelope surrounding the light source varies according to the function of the lamp and the disposition and loading of the filament. As far as possible, the glass is kept well away from the filament to keep its temperature down. This is the reason for the pear shape of the normal type of electric light bulb as used in domestic lighting, photographic flood lighting, enlargers, and similar situations where there are no other factors to dictate another shape.

Fluorescent and cold cathode lamps give off very little heat and can therefore take the shape of a narrow tube.

Quartz-iodine lamps are also tubular and very narrow. The smallest are about ½ inch in diameter and 3 inches long; large types may be up to 3 feet long and about 1 inch in diameter.

The mercury and sodium vapour type of discharge lamp may also be tubular, but in this case the narrow tube containing the vapour is generally surrounded by a larger glass envelope. The space between the two is evacuated to prevent loss of heat from the inner tube and thus maintain the lamp at a more efficient working temperature.

Tubular lamps may be either single or double ended—i.e., they may have both contacts at one end, or one at each. Generally such lamps are double ended because a socket at each end gives a more secure mounting. Light sources of this type may be manufactured in any shape to suit the working conditions—e.g., circular tubes are used in the integrating sphere type of enlarger lamphouse.

Specially shaped glass envelopes are used in certain integral reflector lamps. Reflector flood lamps have a squashed pear shape, with the area of glass immediately behind the filament silvered. This acts as its own reflector.

Internally-silvered projection lamps have a blown-out bulb. The portion immediately behind the filament is ellipsoid in shape, acting —with the internal silvering— as a more or less parabolic reflector. The front of the lamp is also blown out in a spherical shape and internally silvered except for a central window. This silvered area reflects the light from the filament back to the filament and from there to the rear reflector. This ensures that very little light is lost, and all comes out as a more or less parallel beam through the front window. F.P.

See also: *Filament lamp; Flash bulb; Light sources.*
Book: *Modern Electric Lamps*, by D. A. Clarke (London).

LAMPHOUSE. Light-tight (and usually ventilated) chamber holding the light source in projection apparatus—e.g. an enlarger, lantern slide or film strip projector or cinematograph film projector.

The size and shape of a lamphouse is governed by the particular function of the equipment it is part of and the lamp it has to accommodate.

LANDSCAPES

A landscape is a piece of inland scenery. Besides such natural features as hills and trees, fields and hedges, a landscape may include water (river, lake, waterfall) and countryside objects forming a part of scenery, like the village church, cottages, inn, farms; also agricultural operations of various kinds, ploughing, harvesting, etc. The appearance of a landscape is affected by natural effects, e.g., sunshine and storm, light and shade, and by the seasons of the year.

The landscape photographer is presented with the raw materials, and he has to make his picture from them. He does so through a selection of viewpoints by movement within the chosen scene, and by a choice of lighting and seasonal conditions suited to his purpose. His object, generally, is to produce a picture portraying some characteristic of the scene or mood of nature, which will also satisfy the eye.

The first thing to consider is the composition, the setting of the item or items of principal interest in the "frame", and the arrangement of the foreground and the sky. Then the lighting must be studied and the time of day for the best effect chosen, although, unless the photographer has unlimited time at his disposal, this may have to be something of a compromise with the viewpoint.

The landscape photographer, particularly if he is on tour, has to make the best of things as he finds them, or note the required conditions and return another day.

The Principal Interest. A landscape, like any other kind of picture, needs a principal item of interest to which the eye naturally travels. This, as a rule, lies in the distance or middle distance.

The main item of interest may be emphasized

HEIGHT AND DISTANCE OF VIEWPOINT. Top row: *The closer the viewpoint, the more near objects are emphasized at the expense of distant ones. At close range the foreground will only be partly included.* Centre row: *Use of a long focus lens from a more distant viewpoint will still yield large images but without the excessive distortion. As the distance increases further, the proportions will not change appreciably.* Bottom row: *The height of the viewpoint determines the relative placing of foreground and background. From a low viewpoint the foreground and middle distance will fill most of the view. As the camera position goes up higher, the foreground begins to drop away and more distant parts of the scene come into view. From a still higher point the picture becomes virtually an aerial photograph, with no foreground and the increasingly distant planes spread out before the camera.*

by adjusting its tone scale and placing in the final picture. It is not often possible to emphasize it by different focusing, because most lenses render the middle distance and distance equally sharp at all apertures.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

But there is often some atmospheric haze in the air and this splits up the picture into more or less clearly defined planes. This haze lightens the tone and softens the edges of shapes in the far distance. There is less haze between the closer planes and the camera, so the nearer they are, the clearer and sharper they look. And the shadows of nearer objects have a thinner veil of mist over them, so they appear blacker than more distant objects.

This natural separation of the picture planes can be reduced by the use of colour filters.

But the interest must also be prevented from being led out of the picture. Straight, horizontal lines—fences, roads, waterways, and the horizon itself—tend either to divide the picture or to direct the eye out of it. But so long as the line is broken or hidden by some other object before it reaches the margin of the picture, it loses most of its distracting power.

One useful way of keeping the interest within the boundaries of a landscape picture is to frame it with dark foreground objects—e.g., a gateway or overhanging trees.

The Sky. The sky is generally part of any landscape picture, and, in fact, it may provide the main interest. But no matter how much of the picture space it occupies, or whether it plays a principal or secondary part, it must consist of something more than an area of blank paper. Photographic films and plates are almost always over-sensitive to blue light, so unless special precautions are taken, the final print will show no difference in tone between the blue sky and the white clouds. So the sky will be blank and the photograph "baldheaded".

Sky tones can be correctly reproduced—or if

DIRECTION AND ANGLE OF LIGHT. Top row: *The length and depth of the shadows depend on the height of the sun. Low morning or evening sun yields long and luminous shadows; as the sun rises in the sky the shadows shorten, and at midday they are short and intense.* Centre row: *The direction of the sun determines the direction of the shadows and extent of the shadow area. Side lighting casts shadows across the subject, and shows up modelling and texture. Back lighting throws shadows towards the camera which sees the subject almost as a silhouette. Front lighting casts all shadows behind the subject, and produces evenly lit, flat results.* Bottom row: *The different lighting effects are obtainable also by taking the camera round the subject.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

necessary exaggerated, in several ways.

(1) By using a colour filter that holds back the excess of blue rays;

(2) By a special graduated sky filter that filters the light from the sky area only;

(3) By printing in clouds from a separate negative during enlargement; or

(4) By using a polarizing filter to darken a blue sky. This is a particularly useful method when using colour film, where a coloured filter for such a purpose is obviously out of the question.

Figures in Landscapes. Human figures may be included in a landscape photograph, but they should fit naturally into the scene and not be on a big enough scale to become the main interest. Generally speaking, if it is possible to read the expression on the face of any person in the picture, that person will automatically become the subject and the picture will no longer be a landscape study. When people are included, they attract attention out of all proportion to the space they occupy, and a "landscape with figures" is always in danger of becoming "figures with a landscape".

Photographs in towns and cities are apt to look unnatural without people in the streets, but even there, the photographer who includes figures must remember that there is always a strong risk of their stealing the picture.

Viewpoint. The choice of camera distance, viewing direction, and camera height will influence the pictorial effect.

The camera distance determines the scale, and hence the emphasis of the main part of the subject. It does this not only in relation to the picture area (this depends on the angle of view of the lens, too) but also in relation to nearer and farther picture elements. Thus at close range, an object will dominate the foreground and tend to dwarf anything behind. Farther away, the same object will merge into the middle distance or background and lose most of its pictorial significance. (Distance here is considered in comparison to the object size. Thus a gate or fence is in the foreground 10–15 feet away, and becomes an unimportant background feature if it is farther than 50–100 feet. A house at that distance would still be very much the foreground of a larger view.)

The viewing direction largely depends on what aspect of the subject the photographer wants to show. Different sides of a static subject will show different lighting effects, especially early or late in the day.

Deliberate movement of the camera position will also change the relationship between the subject and the background. With near landscapes this can be used to shift prominent features of the skyline (e.g., hills, etc.) to one or other side of the main pictorial interest. In this way foreground objects can be made to cover up disturbing features in the middle distance.

The camera height will determine how much the camera sees of near and distant parts of the scene. A high viewpoint—a bird's eye view—shows the landscape against the ground, with middle distance and background well separated. The nearest features drop out of the picture altogether, and there is little difference in the sharpness of the various picture planes.

From a low viewpoint the foreground crowds into the picture and dominates or even obscures much of what is behind. It also places the nearer features against the sky, and so isolates them from their surroundings.

Lighting. The strength, direction and quality of the light on the scene can make very vital differences in the character of the final picture. There is no need for the photographer to accept these conditions as he finds them; he can control them by choosing the season, the time of day and the weather that will give him the type of lighting he wants. Beyond this, the effect of the lighting at any particular time will depend on whether the camera looks at the scene from the north, south, east or west.

Generally, the most satisfactory lighting for a summer landscape photograph occurs in the hours before 11 a.m. and after 3 p.m. At such times the sunshine falls at an angle, lighting up the sides of things as well as the tops, and casting longish shadows that give them strength, relief and proportion. In the winter the ideal time is between 11 a.m. and 3 p.m.

When the sun is high in the sky, it casts short shadows which are hard and black because there is very little light reflected into them. This type of lighting is too contrasty for good photographic reproduction and it destroys the natural appearance of roundness and solidity that objects should possess in a good monochrome photograph.

When the sun is in front of the photographer, it gives a particular effect known as "contre jour" lighting. In this kind of lighting, shadows are cast towards the camera and most of what the camera sees is in shadow. Such lighting can be striking and dramatic when there are important objects fairly near to the camera, but it is apt to make an open landscape look dull and lifeless.

Camera. Any good-class camera can successfully by used for landscape photography. For controlling perspective, and giving scope for creative composition, interchangeable lenses are invaluable.

Fixed-focus cameras are not very suitable for open landscapes, because their zone of sharpest focus is generally around 20 to 30 feet and they give very poor definition of very distant parts.

The normal camera lens has a focal length about equal to the length of the diagonal of the negative—i.e., it has an angle of about 53°. This type of lens takes in too much foreground and sky for landscape photography where the interest does not lie nearer than the middle distance. It is better to use a lens of longer focal length—i.e., with a narrower angle of view—so that the near foreground and the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PERSPECTIVE AND FOCAL LENGTH. Left: *A short focus lens from a close viewpoint emphasizes perspective and depth.* Right: *A long focus lens from farther away compresses depth and subdues perspective making objects look flat.*

upper sky area are cut out and the important part of the scene fills the negative.

Where the camera lens is not interchangeable for one of longer focus, the unwanted foreground or sky can be left out when enlarging the negative, or trimmed off the finished print.

A lens with a shorter-than-normal focal length—i.e., a wide-angle lens—is sometimes used in landscape photography for special effects, such as exaggerating the size of near objects or conveying an impression of spaciousness.

Exposure. In open landscape photography the lens is usually stopped down as far as possible to give the maximum sharpness and depth of field.

This means that the shutter speed often is the limiting factor. On calm days it is possible to work at shutter speeds of 1/25th second, or even longer if the camera is on a tripod. But if there is a slight breeze, a shutter speed of at least 1/100th second must be used to prevent the movement of branches and eaves from showing, and on a really windy day, speeds up to 1/500th second may be necessary.

If there are people moving about in the scene, nothing slower than 1/100th second should be used.

The direction of the light falling on the scene must also be considered in conjunction with any exposure aid. As a rough guide, the exposure recommendation should be doubled if the light is shining directly from the side, and multiplied by four when shining towards the camera.

If there is running or falling water in the scene, nothing faster than 1/250th second should be used, or the water will look frozen.

Sensitized Material. Medium speed panchromatic film, processed with fine-grain technique, will give big enlargements of good quality.

The really fast emulsions are only necessary in dull weather and very early and late in the day.

Filters and Lens Hood. For general use a medium yellow filter is all that is required to brighten the greens and retain the sky. For dramatic effects, when greater contrast is desired or a bold cloudscape emphasized, an orange filter can be used.

Care should be exercised in the use of a green filter. In spring, when the foliage is light, a green filter will bleach the tone values out of recognition and produce an effect of snow. But later in the year when the greens have darkened, a 2× green filter is invaluable in bringing life to an otherwise dull scene.

For the reason that a person shades his eyes when looking at a distant scene, a lens hood should be regarded as an essential. And in "contre jour" photography it is helpful to hold, or get someone else to hold if the camera is not on a tripod, a map, book or folded paper at a suitable distance from the lens to cast a shadow on it, and thus extend the efficacy of the hood.

Care must be taken to avoid cutting off a part of the picture through the mask being too near.

Colour. Open landscapes taken in colour tend to be disappointing because of the over-all monotonous green, particularly in high summer, with its distant haze.

Spring and autumn are the best times for colour work; spring with its blossom and varying shades of green, and autumn with its galaxy of tints. But it is important to have an appropriate object of principal interest—e.g., a grey stone church, a black and white half-timbered cottage or one of tinted plaster and thatch, a carpet of bluebells, a field of poppies, even a simple white field-gate—to act as a foil to the green landscape. P.J.

LANGENHEIM, FRIEDRICH, 1809–79. German photographer, brother of Wilhelm Langenheim and a relative of F. Voigtländer. Established with Wilhelm a studio in Philadelphia; introduced the Petzval-Voigtländer lens to the U.S.A. The two brothers are always linked historically.

LANGENHEIM, WILHELM, 1807–74. German photographer, relative of F. Voigtländer. Emigrated to Philadelphia, U.S.A. with his brother Friedrich and founded there in 1840 a Talbotype and daguerreotype studio (still in existence a century later under the name of C. W. Briggs Co.). Introduced the Petzval-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Voigtländer lens to the U.S.A. in 1842–3. In 1847 purchased the American rights of the Talbotype patent from Fox Talbot and photographed the Niagara Falls in 1845 on 5 daguerreotypes. From 1850 onwards sold lantern slides (Hyalotypes) which were made by the albumen process of Niepce de St. Victor.

LANTERN PLATE. Photographic plate coated with slow bromide, chlorobromide or chloride emulsions specially made for the production of positive transparencies (lantern slides) from negatives.

See also: *Printing materials; Sizes and packings.*

LANTERN SLIDE. Positive transparency mounted between glass or in a suitable slide frame for projection in a slide projector. The term derives from the time when still projectors were known as magic lanterns.

See also: *Slide (transparency).*

LAROCHE, SILVESTER. 1809–86. French-Canadian portrait photographer with studio in Oxford Street, London. His resistance to Talbot's injunction became a test case in December 1854 when it was proved that Archer's collodion process did not come under Talbot's Calotype patent. As a result, photography with collodion was free for all to practice.

LARSEN, LISA. Dates unknown. American photographer born and educated in Germany. Spoke French, English, German, and some Danish and Russian. Began photographic career in New York and in 1949 joined *Life* as photo-journalist. 1953 Woman Photogapher of the Year; won Matthew Brady Award same year. Career cut short in early life through fatal illness.

LASER. Light source emitting continuous or intermittent light pulses in the form of coherent waves of great concentration and intensity. Also known as optical maser. Laser stands for light amplification by stimulated emission of radiation.

The light produced is extremely pure in colour: its line width is less than 0.03 A—narrower than any known spectral standard. The light waves are coherent: instead of the usual random radiations, they radiate in phase and so can be controlled like radio waves. Output is emitted in a 5-mm. wide beam diverging by less than 0.5°. At 10 kilowatts, this is some 5,000,000,000 times brighter than light of the same wavelength in a similar beam from the sun.

Due to its coherence, it can be focused to a spot of only 10^{-8} sq. cm.

Operating Principle. Lasers utilize the ability of atoms to switch energy levels by respectively absorbing and emitting light energy. The wavelength of this is inversely proportional to the number of levels traversed in one move. Laser action occurs when atoms are "pumped" into a metastable energy level, with intense short-wave light. If they are stimulated into returning to the lowest energy level, the light waves emitted are coherent and have the laser emission characteristics described above. Stimulated from an outside source, the laser behaves as an amplifier; stimulated by its own spontaneous emission, it generates light.

BASIC SOLID STATE LASER. A ruby rod A with semi-silvered ends is surrounded by a flash tube (for intermittent operation) or another suitable light source which provides the "pumping" energy. The laser beam emerges from the end of the rod.

For this, the laser is positioned between two facing mirrors, one partially silvered. Spontaneously emitted light waves are trapped between the mirrors and oscillate through the laser, stimulating further emission which finally penetrates the partial mirror.

Laser Construction. Lasers may be solid, liquid or gaseous and may operate at low absolute temperatures. The first and commonest laser comprises a synthetic ruby rod (aluminium oxide containing chromium), with silvered ends, pumped by electronic flash. This excites the chromium atoms, which emit red light of 0.05 A, bandwidth. Input is some 10 kilowatts and maximum output 1 kilowatt, lasting only as long as the flash. Various other fluorescent metallic crystals are also suitable. Improved pumping methods, using mercury arc lamps, have decreased input and produced continuous emission. Some continuous lasers use helium and neon gas in an ordinary discharge tube with a 50-watt R.F. pumping current. They emit 10 milliwatts, in five infra-red wavelengths, some only 10^{-6} A wide.

Liquid lasers contain benzene or other organic ring liquids. Pumped by ruby lasers, they operate on stimulated Raman scattering—emission wavelength depending on molecular vibrations. They emit red or infra-red radiations and show tunable characteristics. The latest developments are injection lasers, using semi-conductors pumped by ordinary current.

Applications. Lasers are still in their infancy and their usefulness depends on future developments.

Their frequency range may eventually include the whole visible spectrum, leading to variable tuning and bandwidth, besides light

amplification. This offers the photographer a powerful cool light source, tunable to single pure colours or wide mixtures. Available in flash or continuous form, the narrow beam can be condensed to a minute spot.

The latter property has already been exploited in photomicrography. The high-intensity microsecond flash will assist high speed photography and may even make astronomic flash exposures possible, while the spectral purity of the light may make safelights and filters unnecessary. P.B.M.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LATENSIFICATION. Latent image intensification, often called latensification, is very similar to hypersensitizing, but is carried out after exposure and before the negative is developed.

There are three methods of treatment: with a chemical solution; with a chemical vapour; and with actinic light.

Chemical Baths. The baths used for hypersensitizing work equally well as latensifiers. Triethanolamine is particularly effective.

A 0·5 per cent solution of potassium metabisulphite or sodium bisulphite will give an increase in effective speed that can be increased still further by adding an equal quantity of sodium sulphite to the solution.

Treating films or plates after exposure has the advantage that there is no need to dry them again before development. Latensification can, in fact, be the first step in processing, although the speed gain is said to be better if the material is dried after latensification.

Vapour Treatment. Vapour treatment with mercury or sulphur dioxide is exactly the same as for hypersensitizing.

Light Treatment. Latensification by exposure to light does not take place in the same way as hypersensitizing by the same means. At first sight it would seem that the only effect of an additional very small exposure after the true exposure would be to add an imperceptible amount of fog. But, in fact, the effective emulsion speed is appreciably increased.

This is because the light at such very low intensities acts selectively. It is not strong enough to form many new developable image points, but not too weak to go on building up already existing parts of the latent image. By suitable adjustment of the latensification exposure, the latent image exposure can in fact be raised to the upper limit of the threshold exposure for the material in question. A certain amount of fog is also formed, but the gain in the image is much greater.

A darkroom lamp makes a suitable light source, and a dark green panchromatic safelight with a 15 watt bulb has been recommended. The material should be exposed about 15 feet away from the light for anything between 30 minutes and 2 hours. L.A.M.

Book: *Developing*, by C. I. Jacobson (London).

LATENT IMAGE. Exposure to light in a camera does not as a rule produce a visible change in the silver halide grains which, suspended in gelatin, make up the photographic emulsion with which films, plates, and papers are coated. But it does bring about an invisible change which can be revealed by the photographic developer. The invisible image which was present before development is called the latent image, the term latent standing for hidden or invisible. Apart from the process of development, science knows of no other way of revealing the presence of the latent image.

Sensitivity Specks. If exposure is increased very much beyond the level necessary to produce a latent image, the emulsion crystals or grains print out as a visible image because the continued action of light causes the silver bromide to disintegrate into bromine and metallic silver, the latter appearing on the grain surface in the form of small specks. This suggests that the latent image itself is present as small specks of metallic silver on the grain surface.

These specks of silver are extremely small. Their size can be worked out approximately from the ratio of the exposures required for print-out and latent image formation. Such calculations indicate that the mass of a latent image speck is only one part in a hundred million of the whole of the silver bromide grain.

Small as they are, these specks are of fundamental importance in modern theories of latent image formation.

On development, these specks of silver which were formed during exposure act as points of attack for the developer. Starting at the specks, the grains are changed by the developer to black metallic silver, yielding a visible image.

Since the latent image specks are so small that they escape even the most sensitive direct methods known to science, it is no wonder that any theory on the mode of formation of the

IMAGE FORMATION. 1. Silver specks in the silver halide grain. 2. Condensation after continued exposure to light. 3. Developable sub-image. 4. Developed silver image.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

latent image is necessarily speculative, the more so the greater the detail the theory attempts to cover. The general features of any theory are, however, established in broad outlines.

Stages of Formation. The latent image in any one grain is formed in several stages. That means, in terms of the silver speck hypothesis, that several atoms of silver are required to form the latent image. Light (in the form of light quanta; i.e., small parcels of light energy) is absorbed and forms silver anywhere in the silver halide crystal. To form a metallic speck, these silver atoms must flock together. Thus a coagulation or condensation process is an essential feature of latent image formation.

Condensation phenomena are well known in nature and follow well-defined laws. Examples are the formation of water drops to make fog or rain, the growth of snow-flakes and other crystals from solution. When the process of growth is slow, the crystals or particles are few, but large in size; if the process is fast, many but small particles are formed.

Rate of Growth. In the photographic emulsion grain, the rate of growth of the latent image specks is governed by the rate at which light reaches the grain, in other words, by the intensity of exposure. In comparing equal exposures (i.e., in which the product intensity × time is constant) for varying intensities and times, many of the resulting changes in photographic behaviour are accounted for by a straightforward assumption. This postulates that latent image specks formed at low intensities and long times of exposure are few and large and those formed at high intensities and short times numerous and small. One of the most important differences is in the rate of development: flash exposures require longer development than normal snapshots to get full sensitivity and contrast.

During the build-up of the latent image there occurs a stage at which a stable result of exposure is produced which is not yet developable and therefore—by definition—not a latent image. This has been termed the sub-image. The result of a short-time exposure is the production of numerous grains carrying sub-image specks; this causes a considerable sensitization of the emulsion towards a subsequent exposure of longer duration to light of low intensity. Conversely, a low-intensity exposure can build up an image-wise sub-image to a fully developable latent image (latensification).

LATENT IMAGE AND LIGHT INTENSITY. Left: *Short exposure to high intensity forms many small sensitivity specks.* Right: *Long exposure to weak light forms few but large specks.*

LATENSIFICATION. Left: *Exposure to very weak light will build up existing sub-image specks* Right: *The same weak exposure will not form new sub-image specks.*

Reciprocity Failure. The first stage in latent image formation is the most difficult: at low intensities of light, it is the sub-image stage which is inefficient and responsible for the loss of sensitivity for low intensity—long time—exposures (low intensity reciprocity failure).

Crystal growth is much helped by the presence of nuclei on which a start is made. In latent image formation these are provided on the grain surfaces by the sensitivity specks. The nuclei act by holding the first atoms in place; once a reasonable number of atoms have aggregated, the speck is stable. At high intensities the problem of stability does not arise since the specks are built up to stable size quickly. Then even quite ineffective nuclei become operative, and in a photographic grain these are often situated inside where the developer cannot reach them.

The internal image centres come into action if a developer containing a solvent for the silver halide is used. If any surface image present is first bleached away by an oxidizer, the internal image can be studied on its own. With commercial emulsions, the sensitivity on internal development is, as a rule, less than that for surface development, especially for long-time exposures at low intensities.

The formation of the internal image as well as the small size of the latent image specks accounts for the sensitivity loss at high inten-

sities and short times of exposure (high intensity reciprocity failure).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Other Latent Image Aspects. The more detailed theories of latent image formation have to take into account that absorption of light in silver halides produces both silver and halogen atoms. If given a chance these two will recombine to reform silver halide, so that the effect of exposure is lost. The process of chemical sensitization to add speed, is variously regarded as providing places where the silver atoms can collect—the silver-sulphide sensitivity centres of Sheppard and of Gurney and Mott—or chemical acceptors for the halogen atoms (Hickman, Mitchell).

None of the details of the various processes postulated are known with any certainty. There is little doubt, however, that the very first result of the absorption of light in a silver halide crystal is to split an electron from one of the halide ions. This spare electron is freely mobile through the crystal and, in effect, corresponds to the movement of a silver atom through the crystal, since, if the electron stayed with any of the silver ions in the crystal, a silver atom would be formed. If an electron is caught so as to be held tightly somewhere on the crystal, a silver ion could move up to it and form a silver atom there. This appears to be the function of the silver sulphide sensitivity speck, according to Gurney and Mott.

Their theory therefore comprises both an electronic and an ionic movement of which only the second strongly depends on temperature. This accounts for the complicated way in which the sensitivity of photographic emulsions depends on temperature. W.F.B.

LATERAL REVERSAL. Term applied to an image indicating that it has been reversed from right to left. The image of an object seen in a mirror is inverted in this way, so is the image on the ground glass screen of a reflex camera.

Some optical direct viewfinders give a laterally reversed image. A normal negative is both vertically and laterally inverted in the camera, but right and left, and top and bottom, are restored in printing by contact or projection.

Photomechanical printing from blocks does not correct for lateral inversion, therefore the original negative must be made through a reversing prism with the camera at right angles to the copy.

Prints made by the carbon process are laterally inverted unless the negative is first reversed or the print is made by double transfer.

LATITUDE. Term indicating the range of exposure over which a photographic emulsion will yield an acceptable negative. Latitude is directly related to the length of the straight line portion of the characteristic curve and the contrast range of the subject. Generally speaking, the faster the film and the less the subject contrast the greater the latitude.

Very slow films and colour films have practically no latitude; the exposure must lie within very narrow limits (less than half a stop) to achieve perfect results.

Modern high-speed films, on the other hand have an overall exposure latitude of about 8 stops for an average subject; within that range the negative will be acceptable.

LAUSSEDAT, AIMÉ, 1819–1907. French officer of the Engineers' Corps. Pioneer of photogrammetry which he introduced into practice *c.* 1851. He designed or invented many early photogrammetric instruments. In 1861 he produced plans of parts of Paris from photographs taken from the roof of the Polytechnic College and from the tower of St. Sulpice. Same year was appointed Captain of the phototopographic army brigade. Retired in 1879 and became director of Conservatoire des Arts et Metiers in Paris. Wrote a number of books on photogrammetry.

LAUSTE, EUGÈNE AUGUSTIN, 1857–1935. French inventor. Pioneer of cinematography and sound film. Worked from 1887 to 1892 in Edison's laboratory as assistant to W. K. L. Dickson on the Kinetoscope and from 1894 with Major W. Latham on a projection apparatus for moving films. In 1895 constructed his first (wide film) projector, the Eidoloscope, also cameras and a printer. In 1896 joined the American Biograph Co. From 1904 experimented on the recording and reproduction of synchronized sound and movement (pioneer patent of 1907) and showed his first sound film in Brixton in 1910. Made many sound films before the outbreak of the first World War.

LEAD ACETATE. Sugar of lead. Formerly used in combined toning and fixing baths for daylight printing papers, also in certain toners and intensifiers.

Formula and molecular weight: $Pb(CH_3CO_2)_2.3H_2O$; 379.

Characteristics: White crystalline powder, resembling sugar. It is strongly poisonous.

Solubility: Highly soluble in water at room temperature.

LEADER. Beginning of a miniature film used for loading the film into the camera. This is always fogged, and the film has to be advanced by two or three frames after closing the camera in order to bring the first section of unexposed film into position behind the lens. With most miniature cameras the film leader has to be specially trimmed to shape for loading. Film

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

TEMPLATE FOR FILM LEADER. Some miniature cameras need specially shaped film leaders for loading; these may be cut accurately with the aid of a suitable template.

supplied in cassettes or refills has the beginning already suitably trimmed. Special trimming templates are available for trimming film cut from bulk lengths.

With narrow-gauge cine film the film leader is the initial length used for threading the film through the transport mechanism and on to the take-up spool of the cine camera or projector.

Such a leader, especially on 16 mm. release prints, carries certain reference information about the film as well as cue frames for the precise location of the film in the projection gate. This permits a smooth start to be made to a performance.

The required location and nature of such cues, and the length of the leader, are laid down by various national and international standards. This applies also to 35 mm. motion picture film. Similar leaders are provided on still film strips produced for educational and instruction purposes.

LEAD NITRATE. Formerly used in combined toning and fixing baths for daylight printing papers, also in certain toners and intensifiers.

Formula and molecular weight: $Pb(NO_3)_2$; 331.

Characteristics: White crystals. Strongly poisonous.

Solubility: Highly soluble in water at room temperature.

LECTURES. Still and cine projection can be used to illustrate lectures for entertainment, education and instruction. The simplest arrangement is to have a projectionist projecting slides when required (and signalled by the lecturer) to show specific points made. For more elaborate arrangements the projector can be remote operated by the lecturer himself, or the lecture recorded on tape which also controls the slide projector by means of cueing signals.

LE GRAY, GUSTAVE, 1820–62. French painter and photographer, inventor of the waxed paper process 1851. A founder member of the Societé Héliographique. Took a large number of photographs for the Commission for Historic Monuments, 1851. Famous for his instantaneous seascapes, 1856 and wrote several *manuels* of photography. Retired from photography early in 1861 because of the carte-de-visite vogue, and became professor of drawing in Cairo.

LEICA. First modern 35 mm. miniature camera. An unnamed prototype was built by Oscar Barnack in 1914 for his private use, to take photographs on the standard film used in commercial cinematography. In 1924 Ernst Leitz of Wetzlar started manufacturing the camera. The first model had a fixed lens, a focal plane shutter, coupled film transport and shutter tensioning. It used 35 mm. film in special cassettes which were inserted into the camera in daylight. Subsequent models retained the same principles and basic construction, but incorporated various refinements such as interchangeable lenses, coupled rangefinder focusing, an extended range of shutter speeds, and flash synchronization.

The Leica also originated miniature photography which, owing to the unusual technical requirements and novel scope of that type of camera, existed for a long time largely as a separate photographic movement.

The Leica was also the first camera to be used as the basis of a camera system planned to cover practically every field of photography by the use of an extensive range of accessories and specialized photographic equipment. Although many miniature cameras have followed this lead, the Leica system is to-day still one of the most comprehensive and versatile.

LEITZ, ERNST, 1843–1920. German optician. Established in 1869 the Ernst Leitz optical works in Wetzlar. Specialized in the manufacture of microscopes, prism binoculars and other fine-mechanical instruments. Biography: *Jubilee Book*, 1849–1949, edited by A. Berg (Wetzlar 1949).

LEITZ, Dr. ERNST, 1871–1956. German, son of Ernst Leitz, who succeeded his father as head of the Leitz works in Wetzlar, Germany, in 1920. Expanded production lines to include industrial optical measuring instruments and photographic equipment. Manufactured the Leica camera (invented by Oskar Barnack 1913) from 1924. Biography: *Jubilee Book*, 1849–1949, edited by A. Berg (Wetzlar 1949).

LENDVAI-DIRCKSEN, ERNA, 1884–1962. German portrait photographer. Her most important work was the large number of volumes of *Das Deutsche Volksgesicht* published in the 1930s, consisting of portraits of typical German peasants in their regional costumes.

LENS

CC-0.Agamnigam Digital Presevation Foundation, Chandigarh

Optical device for forming an image of an object. In photography, the lens always consists of a portion of a transparent medium—e.g., glass or plastic—bounded by either two curved surfaces, or one curved and one plane.

When rays of light pass from one transparent medium into another, their direction of travel usually changes—i.e., they undergo refraction. When they pass at an angle into a denser medium, then the rays are bent towards the normal (a line perpendicular to the surface at the point of entry of the ray). If the rays are themselves normal to the surface they suffer no refraction. When the rays emerge from the denser medium, they are bent away from the normal unless themselves normal to the surface.

If the surfaces of the denser medium are parallel, then the refraction at entry is reversed at exit so that when the ray comes out, it is still parallel to its original direction but displaced to one side or the other by refraction inside the medium. But if the surfaces of the medium are not parallel, then the refraction at entry will no longer be exactly reversed at exit, and the incident and emergent rays will no longer be parallel. In other words, the light ray after passing through the medium will be bent at an angle to its original direction; and the greater the angle between the surfaces of the medium, the more it will be bent. This is the basic principle of the lens.

Simple Function. A lens is simply a glass disc shaped so that rays from a point object on one side pass through and are bent either inwards towards a common point on the other side of the lens, or outwards as though radiating from a point closer to the lens than the object. This is achieved by shaping one or both faces of the disc like a portion of the surface of a sphere.

If the curves are so arranged that the lens is thicker in the middle than at the edges, parallel rays of light falling on it will converge to a point on the opposite side. It is then called a converging lens.

If the curves are so arranged that the lens is thinner in the middle than at the edges, parallel rays of light falling on it, when seen from the other side, will appear to radiate from a point. It is then called a diverging lens.

Since any object can be considered as a collection of points, then a converging lens, by producing point images of all the object points, forms an image similar in all respects to the object. If a light reflecting surface is placed in the plane of the image points, a visible image of the object will be formed on it. This, in fact, is the type of image formed on the focusing screen of the camera and which registers as a latent image on the sensitized material during exposure. Such an image is said to be a real image.

A diverging lens does not form a real image; the rays of light from the object are not bent inwards after refraction: they open out so that they appear to come from a point nearer than the object. This point is merely apparent; it is not real. So the image formed by all the points is called a virtual image; it cannot be made visible on a reflecting surface like a real image.

Lens Shapes. The behaviour of the lens varies according to the number of curved surfaces and the direction of the curvature. When both surfaces are convex or there is one convex and one flat face, the lens is always a converging type. When both are concave, or there is one concave and one flat side, the lens is always a diverging type. When there is one concave and one convex side the lens may be either converging or diverging depending on the relative curvature. If both sides have the same radius of curvature the lens is neither diverging nor converging. Each type has its special uses and each has a distinguishing name:

TYPES OF LENSES

Plane	*Convex*	*Concave*	*Name*	*Thickest at*	*Effect*
1	1		Plano-convex	Middle	Converging
1		1	Plano-concave	Edges	Diverging
	2		Bi-convex	Middle	Converging
		2	Bi-concave	Edges	Diverging
	1	1	Concavo-convex	Middle	Converging
	1	1	Concavo-convex	Edges	Diverging

FOCUS OF CONVERGING LENS. A converging lens bends parallel rays of light so that they converge to a point of focus situated at a fixed distance behind the lens.

FOCUS OF DIVERGING LENS. A diverging lens bends parallel rays of light so that they diverge and appear to come from a point of focus in front of the lens.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

LENS SHAPES. Top: Converging lenses. A, plano-convex. B, bi-convex. C, concavo-convex (meniscus). Bottom: Diverging. D, plano-concave. E, bi-concave. F, concavo-convex

In practice lenses may be either simple—i.e., a single shaped glass—or compound—i.e., an assembly of glasses with characteristics intended to balance out certain inherent shortcomings of the simple components.

A simple lens is known as a lens element. A combination of two or more elements which still makes up only a part of a complete optical system is a lens component. This term is also applied to separate uncemented lenses used on their own in an optical system. Thus a camera lens may for instance consist of four elements; if two of those elements are cemented together and the other two stand free, the lens is said to have three components.

There are a number of basic optical relationships which, with certain modifications, apply to both simple and compound lenses.

The Principal Focus. The straight line about which the lens or objective is symmetrical is called the axis. The centres of curvature of all the curved faces of the lens lie on the axis.

When rays of light pass through a converging lens parallel to its axis, as though coming from a point very far away—i.e., at infinity—they are bent inwards and meet at a point on the axis. This point is called the principal focus of the lens. Light passing through a diverging lens in the same way is bent outwards so that it appears to come from an imaginary point on the other side of the lens. This point also is called the principal focus of the lens.

The principal focus of a converging lens is a real point and the image formed by the lens is a real image that can be focused on a screen. The principal focus of a diverging lens is not a real point in the same sense, and the image cannot be made visible by projecting it on to a screen. This type is known as a virtual image.

If the rays of light pass through the lens in the opposite direction, they reveal a second principal focus on the other side of the lens. The planes at right-angles to the lens axis which pass through the principal foci are called the principal focal planes of the lens. Both the principal foci lie on the axis of the lens.

They are also known as the front principal focus and back principal focus, according to the orientation of the lens. By standard definition the front of a camera lens is that end which is intended to face the object being photographed, while the back of a camera lens is the end which faces the sensitized material and the focal plane of the camera. When the front of the lens faces an infinitely distant object, the light rays from the latter converge at the back principal focus. Hence the other principal focus is the front principal focus.

The front of an enlarger lens is that end of it which is intended to face the baseboard of the enlarger, while the back is the end facing the negative being enlarged. The principal foci are therefore disposed accordingly.

Usually lenses have plane or spherical surfaces since these are easy shapes to grind and polish, but sometimes non-spherical (aspheric) surfaces are used.

NODAL POINTS. A composite lens behaves as if it were a simple lens which receives the light at one point and discharges it at another. These two points are the nodal points, and the dotted lines passing through them are the principal planes. O, object. I, image. N_1, front nodal point. N_2, rear nodal point. U, object distance. V, image distance.

CC-BY. Agamnigam Digital Preservation Foundation, Chandigarh

Focal Length. The distance from the centre of the lens to the principal focus is known as the focal length of the lens. This is the distance at which all parallel rays of light—i.e., those coming from a very distant object—converge to form a sharp image on a film or plate. If the object is closer, then the image will be formed farther away from the lens.

If the object is at infinity, the lens-plate distance that gives the sharpest image is equal to the focal length of the lens. If the object is closer than infinity, the required distance is always greater than the focal length. Finding the distance that gives the sharpest image of a particular object is known as focusing the lens.

If the focal length of the lens is known, the lens-plate distance can be calculated from the basic equation:

$$\frac{1}{u} + \frac{1}{v} = \frac{1}{F}$$

where u = distance from the object to the lens
v = distance from the image to the lens
F = focal length of the lens.

This equation is not very convenient for calculations and adaptations are more often used.

Equivalent Focus. Like simple lenses, compound lenses—i.e., with more than one component—have their principal foci found in the same manner by determining the position of the image-point of a distant object on the axis of the lens.

Simple lenses are treated as though they have no thickness, and it is assumed that the object-lens and lens-image distances are measured from the centre of the lens. Compound lenses cannot be treated as though they have no thickness, and in calculations on compound lenses, the object distance is measured from one fixed point in the lens and the image distance measured from another. These points are called the nodal points of a lens and the planes through them at right-angles to the axis are called the principal planes. The distance from the second nodal point to the rear principal focus is the equivalent focal length of the lens; the distance from the first nodal point to the front principal focus is also the equivalent focal length of the lens.

The equivalent focal length governs the size and position of the image formed in the same way as the focal length governs the size and position of the image formed by a simple lens.

For all optical calculations such as those based on the equation

$$\frac{1}{u} + \frac{1}{v} = \frac{1}{F}$$

the object and image distances are measured from the nodal points, and the value given to F is the equivalent focal length of the lens.

When the lens is part of a camera, it is more convenient to define the image position for a distant object in terms of the distance from the surface of the rear element to the rear principal focus. This distance is called the back focal distance of a lens. There is also the corresponding front focal distance.

Nominal Focal Length. While lenses for cameras, etc., are normally designed for specific focal lengths, the actual focal length of a series of similar lenses as manufactured may vary slightly owing to manufacturing tolerances. In most cases (except where photographs taken with the lens require precise dimensional valuation) this is unimportant provided the other lens calibrations (especially the distance scale) are adjusted accordingly. Thus a standard lens for a 35 mm. miniature camera may be listed as having a focal length of 50 mm.; the lenses actually produced may range in focal length from 48 to 52 mm., and the lens maker does not generally mark such deviations. By international standards the acceptable measured focal length may be within plus or minus 4 per cent of its marked nominal value.

Focal Length and Field. If a comparatively large image is required, a lens of long focal length is used, since this produces a larger image than one of short focal length. At the same time, for a given negative size, the larger the image formed by the lens, the smaller the proportion of the field which will be recorded on the negative; so in practice the final choice of focal length is controlled by the amount of the field that the lens is to cover, or its angle of view.

The exact relation of the field covered to the focal length of the lens is given by the equation

$$2F \tan \frac{\theta}{2} = d$$

where F = equivalent focal length of the lens
θ = total angle of field subtended by the object at the lens
d = diagonal of the negative.

The field of photographic lenses generally lies between 15° and 140°. Within these limits lens designers have produced a wide variety of lenses, each one with a particular purpose to fulfil. Thus a lens which is designed for a 30° field gives poor results over a 50° field, and although a 50° angle lens has quite a good performance over a 30° field, it is never as good as a lens designed to cover 30° and no more.

The angle of a lens gives very little indication of the general type of construction—e.g., Speed Panchro lenses of various designs have fields of from 14° to 53°, while triplets vary from 25° to 70°.

However, for fields greater than 70°, special wide-angle lenses are made. These are generally variations of the symmetrical type of construction. A good modern wide-angle lens may cover an angle of as much as 100° at *f*32. Such a lens has a maximum aperture of *f*6·3, which is, however, used only for focusing. Special wide aperture lenses are available to cover 70° to 80° at apertures as great as *f*4·5.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FOCAL LENGTH AND SCALE. Top: *A lens of short focal length, f_1 produces a smaller image of an object a given distance away, but covers a greater part of that object.* Bottom: *A lens of longer focal length f_2 yields a larger image of the same object at the same distance in front of the lens, but on a similar negative size will include a smaller object area.*

Normally a lens of very long focal length requires a long camera extension. This is undesirable, and has led to the development of the telephoto lens which has a long focal length, but which works with a normal amount of camera extension.

The power of a telephoto lens is defined as the ratio of its equivalent focal length to its back focal length. This ratio is increased by making the lens of two widely separated components. The front component causes the light to converge, while the back component is divergent. In the most modern designs, both the front and rear components are quite complex.

Telephoto lenses of early forms suffered from severe distortion, but this was considerably reduced in later designs. An average modern telephoto lens will work at an aperture of *f* 5·6 and cover a field of 15° to 30°.

Aberrations. All lenses suffer more or less from basic shortcomings inherent in their design and construction which prevent them from forming a perfect image of the subject. These imperfections, known as aberrations, are of a number of distinct kinds, and are eliminated or reduced by the lens designer in various ways—e.g., by introducing extra lens components with equal and opposing aberrations.

The process of reducing the aberrations is known as correcting the lens and the further it is carried the more expensive it becomes. In practice a lens is corrected only just enough to meet the specification laid down; to go beyond that point would simply multiply the cost of the lens to no good purpose.

It is because of the lens aberrations that the distinction between the front and the back of a lens becomes significant. Lenses are corrected for the conditions under which they are intended to be used. Thus a camera lens is normally used in such a way that the front focal distance is very much greater than the back focal distance, in other words with reasonably distant objects. When these conditions are reversed, for example in macrophotography where the image distance becomes appreciably greater than the object distance, the lens may no longer yield its best performance. In such a case it is sometimes useful to reverse the lens, and use it with its front facing the sensitized material and the back facing the object.

Due to the residual aberrations in the lens, the focal length as measured with light passing from the front to the back may be different from the value obtained with the light passing from the back to the front. The former value is known as the back focal length, and the latter value the front focal length. When the term focal length is used without qualification, it is normally understood to mean the back focal length.

An enlarging lens, by the same token, is normally intended to be used with the front focal distance (lens-to-enlarging paper) greater than the back focal distance (lens-to-negative). Special lenses, for example for process work, are often corrected to perform best under conditions where the front and back focal distances are more or less the same or do not exceed a ratio of about 3 : 1 or 4 : 1.

Calibrated and Computed Focal Length. The focal length of a lens also determines the image scale, in other words the magnification under specific conditions. If the lens suffers from distortion—one of the various aberrations—the image scale is no longer constant over the whole of the image. It may then be necessary, in certain applications of a lens, to assume an adjusted value of the focal length. This is chosen to distribute the distortion in a manner best suited to the conditions under which the image is valuated. This adjusted value is known as the calibrated focal length. It is used mainly in the calculations involved in measuring dimensions from the image formed by the lens under specified conditions.

When complete constructional data of a lens design (such as the curvatures, refractive indices, thicknesses and separation of lens elements) are available, the focal length of a lens can be completed mathematically as the distance from the rear nodal point to the principal focus. This is the focal length for a light beam of negligible diameter parallel with the axis of the

lens. Such a limitation to a narrow axial light ray eliminates the influence of aberrations on the focal length; the latter may be different from the actual focal length measured.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Aperture and Diaphragm. It is generally necessary to be able to control the amount of light that passes through a lens—e.g., as a means of adjusting the exposure. This is done by placing a diaphragm with a hole in it in the path of the light rays. The size of the aperture can be varied according to the amount of light that is to be allowed to fall on the sensitized material to make the exposure. The control which alters the size is calibrated in *f*-numbers. The *f*-number at any setting is the ratio of focal length to effective optical diameter (which is not necessarily the same as the physical diameter of the lens opening); it is thus a relative measure of the aperture. The brilliance of the image varies in proportion to the *f*-number; it does not depend upon the actual size of the lens or its diameter. So all lenses set to the same *f*-number form images of equal brilliance and hence call for the same exposure, no matter what their focal length.

The diaphragm has another function: it controls the depth of the field of sharp definition within which any focused object lies. The smaller the aperture, the greater the depth of field sharply covered.

The aperture also gives control of certain types of aberration, and all lenses require a diaphragm to restrict their useful area in some degree for this reason.

APERTURE AND FOCAL LENGTH. Top and centre: Two lenses of the same diameter but of different focal length produce images of different sizes and therefore of different brightness. Bottom: As the lens is stopped down, the brightness of the image decreases still further.

Coating. When a lens is composed of a number of elements, the amount of light lost through reflection at each of the surfaces may add up to a serious amount of the image-forming rays. Most of this loss is prevented by the process of coating or blooming the lens surfaces with a thin film of a suitable metallic fluoride. Practically all lenses are now treated in this way.

Special Lenses. In some cases lenses are required with special characteristics—according to the particular work the lens is intended for. Lenses designed for such purposes are usually named according to their function—e.g., enlarging lens, process lens, projection lens.

There are also lenses which are designed to produce special effects. These involve quite unusual constructions rather than just differences in normal characteristics. Instances are: the Hill cloud lens, designed to cover a field of 180 degrees so that the sky can be photographed on one negative; the variable focus lens, used to get continously variable focal lengths, and thus image sizes; the Fresnel lens—a simple lens of unusual shape—intended for spotlamps.

Engraved Data. All lenses of any value have certain information on the the rim of the mount.

A recommended standard form of marking lists the focal length, maximum aperture, name of lens maker, name of lens, and maker's serial number. For example: 50 mm. *f* 2·8 Smith Anastigmat No. 12876. Certain alternative marking systems are also in use, including the town of the lens maker, and different ways of expressing the maximum aperture (e.g. as a ratio of aperture diameter to focal length): G. Smith, Leeds, Anastigmat, *f* = 50 mm., 1 : 2·8, No. 12876.

The iris diaphragm control is also marked with the different aperture settings, normally chosen from the international standard aper-aperture range. Sometimes the maximum aperture does not fall into the international standard range; the older continental aperture range is, however, now obsolete.

Where the lens has a distance scale, this may be marked in either feet or metres or both. A standard recommendation is that the distance figures should follow the series H, H/2, H/3, H/4, etc. (H is the hyperfocal distance at full aperture, i.e. the nearest distance within the depth of field range when the lens is focused on infinity.) Lenses do not necessarily follow this recommendation. D.P.C. (L.A.M.)

LENS CAP. Opaque metal, rubber or plastic cover slipped over the camera lens to protect it. Interchangeable lenses are usually supplied with a cap for both ends, for complete protection, when the lenses are detached from the camera. With early cameras which had no shutters the photographer made the exposure by uncapping the lens for the required time. This method is still used for making long exposures with stand cameras.

Some hand cameras have a baseboard which covers the lens when the camera is folded, in which case no lens cap is required.

LENS CARE. The optical glass used for making lenses is usually much softer than other kinds. It is not easy to clean once it has been allowed to get dirty; everything should be done to keep it clean in the first place. If the lens has a lens cap, it should be left on unless the camera is actually being used; if the lens is detachable, it should have a cap over each end when it is out of the camera. Folding cameras should never be left open when they are not in use.

The lens surfaces should never be touched with the fingers. Fingers leave greasy prints that dust will stick to, and may leave acid perspiration that will actually destroy the high polish.

Dry dust is best removed from the lens with a soft camel hair brush or by blowing it off with an air jet from a watchmaker's bellows—not by breathing on it.

Grease and finger marks may be removed by wiping the surface gently with a piece of soft, well-washed cotton rag or wash-leather. The special tissues made for cleaning lenses are excellent; they can be used once and thrown away, so that there is no danger to the lens surface from dust and grit picked up and embedded in the tissue.

A stubborn film over the lens may call for a drop of methylated spirit on the cleaning tissue. No spirit should actually flow on to the lens or it may penetrate between the cemented components and loosen them.

When, through wrong cleaning methods, a lens has lost its high polish, it should be returned to the maker for repolishing; no one but a specialist should tackle this job which requires precision equipment.

LENS HISTORY

The lens in its simplest form has been known for hundreds of years; references to the use of a magnifying glass occur in writings of the eleventh century. The first use of a lens in a camera, however, was probably in the camera obscura of Cardano in 1550; the lens was of biconvex form and made of crown glass. Chemical recording of the image was unknown; it was simply viewed on a screen, often a marble table-top. No attempts were made to correct the lens for the various optical aberrations, and the photographic lens really originated in 1812, when the English physician, Wollaston, first recognized one of the most important principles in lens design—that certain aberrations could be controlled by suitably positioning a stop with respect to the lens.

The Wollaston meniscus gave reasonable definition at *f* 16 over a field not greater than 50°. More simple meniscus photographic lenses have been made than of any other form, for use in fixed focus box cameras. Wollaston's lens was uncorrected for colour, and the achromatized meniscus was introduced by Chevalier in 1829, the principle of combining a positive lens of crown glass with a weaker negative element of flint glass having been already applied to the telescope object glass.

The period 1840–60 saw the birth and growth of photography, as in those years great strides were made in the chemical recording of the image formed by the camera lens. The advantage of a fast lens—that is, a lens of large relative aperture—was now obvious, and ensuing developments had this aim, together with improved definition over a larger angular field.

Petzval Lens. Recognizing the need for lenses of increased speed, the Hungarian mathematician J. Petzval, in 1840 made a complete break from the traditional lens type of his day and evolved the Petzval lens with a relative aperture rated at *f* 3·6, possibly basing his design on the Fraunhofer telescope objective. The lens had good correction of spherical and chromatic aberrations and coma, but astigmatism and field curvature were considerable; the lens was most suitable, therefore, for portraiture requiring high aperture but small field and established itself at once as the best portrait lens all over the world. Many years later it was developed for high-speed taking and projection lenses in cinematography.

Orthodox Development. Few attempts were made to develop the Petzval lens on its introduction, possibly because designers were intent on evolving lenses with large angular fields rather than high relative apertures, and a period of some eighty years elapsed before a lens of higher aperture was produced.

Following the lead of Wollaston and Chevalier, the next fundamental advance was the introduction of the symmetrical type of lens to give reduced distortion and coma. The Goerz Hypergon appeared in 1900, and consisted of two meniscus lenses of equal power symmetrically placed on either side of a stop. The coma contributions of the two elements were equal but opposite in sign, and distortion was small if spherical aberration was also small—that is, at low aperture ratios. Spherical aberration was considerable, chromatic aber-

ration uncorrected and the field was limited to angles to be covered but the large residual spherical aberration restricted the useful aperture. Reasonable definition was obtained at *f* 30, and it was claimed to be usable over a field of 135°. The Hypergon was, in fact, the first wide-angle lens.

Of historical interest is the Panorama lens introduced by Thomas Sutton at about this time, and consisting of a hollow glass sphere filled with liquid (water or acids). It was of symmetrical form as it had a central stop, and was fitted with a butterfly diaphragm to give more uniform illumination over the plate. It covered a field of 120° at *f* 12. In 1862 appeared the first achromatic symmetrical-type lens, the Globe lens of Harrison and Schnitzer. The outer glass surfaces were concentric, and the lens covered 92° at *f* 17·5. Better known, however, are the lenses simultaneously introduced in 1866 by Steinheil in Germany and Dallmeyer in England; the latter's Rapid Rectilinear had a relative aperture of *f* 8, but the field was limited to 40° or 50°, and even over this angle was heavily curved. A wide-angle form of the R.R. was introduced to cover a field of 100° at *f* 15.

Early Anastigmat Period. Lens designers at this time were handicapped by limitations set by the optical glasses available: to satisfy the conditions for achromatism and flatness of field, glasses were required in which high refractive index was associated with low dispersion, whereas, in the crown and flint glasses then used, high index went with high dispersion. In 1888 Abbe and Schott in Germany produced stable glasses with the desired properties, and soon afterwards Schroeder published the design of the Ross Concentric. This lens was the first anastigmat—that is, the field (70°) was reasonably flat and tolerably free from astigmatism—and consisted of two achromatic doublets using the new barium crown glass of high index and a new flint glass of low index. This combination, however, was the opposite of that required for correction of spherical aberration, and the lens could be used only at the small relative aperture of *f* 16.

This difficulty was overcome by Rudolph, of Zeiss, who in 1890 introduced the Protar, combining an old achromat on one side of the stop to correct spherical aberration with a new achromat on the other side to correct astigmatism. The lens worked at *f* 7·5. In 1894 improved corrections were obtained in the Double Protar, in which the old and new achromats were cemented and duplicated on either side of the stop. Von Hoegh of Goerz achieved a similar result with six elements in the Dagor, working at *f* 6·8 over a field of 70°.

The symmetrical form was retained at this time to reduce coma and distortion, but each half could be used separately, with poorer correction, giving lenses of different focal lengths. The complete lens was then called a convertible. These symmetrical type anastigmats had similar properties; the relatively flat

Cooke Triplet and Derivatives. Possibly the most fundamental advance in lens design was made in 1893 by H. D. Taylor in the Cooke lens. Curvature of the field depends on the resultant sum of the powers (with due respect to sign) of the separate surfaces of a lens system. H. D. Taylor first took a positive and a negative lens of approximately equal powers, so that the field curvature was small, and separated them sufficiently to give a resultant positive lens. To correct distortion he divided the positive element into two, placing one part on each side of the negative member. To achromatize a system for points off the axis it had been considered essential to achromatize each component separately; H. D. Taylor discovered that the system could be achromatized as a whole. Spherical aberration and coma were corrected by suitable choice of curves, and astigmatism by placing the stop near to the negative component. The lens worked at *f* 3 and covered a field of 40°; it was, therefore, considerably faster than contemporary designs—e.g., the Dagor—but covered a smaller field. Later, more symmetrical types were introduced to cover wider angles.

The Cooke Triplet provided a construction capable of adaptation in symmetrical and unsymmetrical forms. Most modern anastigmats are derived from it, the tendency being towards the symmetrical form with its better field correction. In the Aldis Anastigmat at *f* 4·5 the front components were cemented. A well-known derivative of the triplet is the Zeiss Tessar introduced by Rudolph in 1902; a doublet rear member is employed, and the lens originally worked at *f* 4·5 over a 50° field. The aperture has been increased to *f* 3·5 without serious deterioration in definition. The Leitz Elmar is a Tessar type, as also is the Kern Anastigmat; the latter is used over a field of 65°. The Ross Xpres can be regarded as a development of the Tessar type, having a triple-cemented back component.

In the Voigtländer Heliar the front and back components are doublets, as also are those of the Booth (Dallmeyer) Pentac with a relative aperture of *f* 2·9. The Hektor, due to Berek of Leitz, utilizes three doublet components and works at *f* 1·9. In the Zeiss Sonnar *f* 2 and *f* 1·5 lenses, triple-cemented components are used; the angle covered is 48°. In a relatively simple derivative of the triplet, Lee (1926) increased the aperture to *f* 2·5 by using a double-back component in the Taylor-Hobson Cooke Series X.

Quadruplet Types. Whilst H. D. Taylor in the Cooke Triplet had actually divided the positive lens into two components, he also suggested that the negative lens could be similarly divided and the two parts placed on either side of the stop, the resultant system being of a symme-

trical type, more suited for larger angular fields. This form was developed by Goerz in their Celor and Dogmar lenses (1898) and further developed by Warmisham about 1914 into the Taylor-Hobson Aviar working at $f4{\cdot}5$. In the Ross Homocentric all four components are of meniscus form, and the lens works at $f5{\cdot}6$ over a 50° field.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The demands of the cinema industry and of the miniature camera user were for faster lenses with a high standard of definition. By employing doublet negative lenses, Rudolph increased the aperture to $f3{\cdot}5$ in the Zeiss Planar, and in 1920 Lee increased it still further to $f2{\cdot}0$ in the Taylor-Hobson Series O. The Leitz Summar, the Schneider Xenar and the Zeiss Biotar are all of similar construction. Departure from symmetry and increase in complexity are shown in the $f1{\cdot}3$ lens, due to Warmisham, and the $f1{\cdot}0$ lens, due to Lee.

The quadruplet lens with meniscus components is particularly adaptable to a wide-angle form at a moderate aperture. The Zeiss Orthometar introduced in 1931 and the Ross Wide-angle Xpres have a relative aperture of $f4$ and cover a field of 70° with very good distortion correction. The Zeiss Topogon, introduced in 1933, covers 90° at $f6{\cdot}3$, and a similar form is made by Bausch and Lomb as the Metrogon. The Ross $f5{\cdot}6$ wide-angle survey lens has the rear positive component divided into two elements.

Petzval Derivatives. The Petzval type of lens, characterized by large aperture but small field, remained largely undeveloped for many years. Designers were at first attracted more by the potentially better field correction of the symmetrical type, and later by the even greater potentialities of the triplet construction. For portraiture, however, the lens remained popular for a long time. The demand of the cinema industry for projection lenses with large apertures but relatively small angular fields ultimately aroused interest in its capabilities. Most cinema projection lenses are of the Petzval type with relative apertures up to $f1{\cdot}9$. When larger angular fields are involved, as in back projection, the lenses are usually triplet derivatives.

As a high speed taking lens for cinematography the type was developed by Warmisham to $f1{\cdot}3$; and for radiography to $f0{\cdot}85$ by Zeiss and to $f0{\cdot}83$ by Lee.

Telephoto Lens. The telephoto principle was applied by Barlow to telescopes in 1834, and to photographic lenses in 1891 simultaneously by Dallmeyer in England, Duboscq in France and Miethe in Germany. Dallmeyer first introduced a complete telephoto lens, consisting of an achromatic positive component and a triple negative. This was too slow, and was superseded in 1892 by a symmetrical triple negative lens to be used with a (positive) portrait lens of the Petzval type. A year later he introduced a negative attachment consisting of a pair of negative doublets and considered particularly suitable for medium magnifications. Several firms marketed their own versions of these negative attachments. Variation of focal length of the combination was obtained by altering the separation of the negative attachment and the positive lens with which it was used. These combination lenses were unsatisfactory, since field curvature and astigmatism were over-corrected (that is, the field was convex towards the lens), pincushion distortion was prominent and oblique colour was objectionable.

In 1898 Rudolph of Zeiss reverted to the original aim of Dallmeyer and introduced a telephoto lens complete. Dallmeyer in 1901, followed by Plaubel in 1905, introduced another type of attachment in the form of a low-power Gallilean telescope. The Dallmeyer attachment was called the Adon and had a magnification of three; it was not completely telescopic, and could be used alone as a telephoto lens of small aperture. This type of attachment was considered particularly suitable for use with the small lenses fitted to hand cameras with limited bellows extension. In more recent times a Gallilean attachment has been introduced by Schneider, and is mainly intended for use with lenses working with 8 mm. and 9·5 mm. film.

Fixed Focus Telephotos. The first successful fixed focus telephoto lens, capable of replacing the usual lens on the hand camera and giving a larger picture with the same bellows extension, was probably the Bistelar introduced by Busch in 1906. It had a relative aperture of $f7$ or $f9$, depending on the focal length, and a telephoto effect of two, and was followed by the Zeiss Magnar of $f10$ and a telephoto effect of three.

In 1910 Dallmeyer produced the Grandac, and in 1912 Booth offered the New Large Adons with relative apertures of $f4{\cdot}5$ and $f5{\cdot}6$ and of similar form to the Bistelar. The Telecentric of Ross, with apertures of $f5{\cdot}4$ and $f6{\cdot}8$, had a triple positive component. These telephoto lenses were free from many of the defects of the variable magnification types, but still suffered from astigmation and distortion.

Anastigmat Telephotos. The first anastigmat telephoto lens was designed by Booth in 1914 with an aperture of $f6$; it was corrected for flatness of field and astigmatism, as well as for spherical and chromatic aberrations, and in definition was a considerable improvement on its predecessors. In 1920 the same designer lightly simplified the construction by using a cemented positive component, and the lens was made by Dallmeyer as the Dallon with an aperture of $f5{\cdot}6$ and a telephoto effect of two. The Zeiss Teletessar at $f6{\cdot}3$ also consisted of two cemented components, whilst the Ross Teleros at $f5{\cdot}5$ has a triple cemented negative component. By separating the positive com-

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

ponent into two elements (one cemented) Lee increased the aperture to f 3·3.

Distortion had been considered an inherent drawback of the telephoto construction, and was present in all of the types mentioned. The first distortion-free telephoto lens was designed by Lee, with an aperture of f 5 and a telephoto effect of 2·3. The field covered by anastigmatelephoto lenses is usually 30°. For cinematography, the aperture of the telephoto lens has been advanced to f 1·65.

Inverted Telephoto Lens. In the telephoto construction with the positive component in front of the negative the equivalent focal length is greater than the back focal distance: with the negative component in front of the positive the focal length is less than the back focal distance. For a given focal length, therefore, the inverted telephoto construction gives a greater back clearance, a convenient arrangement if it is necessary to interpose other optical elements between the lens and the focal plane. In some systems of colour cinematography, for example, a beam splitting prism has to be accommodated in this space. One such inverted telephoto design, due to Lee, is used for photography in Technicolor; a lens of 1½ ins. focal length covers the 35 mm. film frame, with an aperture initially f 2 and later increased to f 1·7.

Another effect of the inverted telephoto construction is a widening of the angular field, and this property has been utilized by R. Hill in his Cloud lens for photography of the whole sky, the field covered being 180° at a very small aperture; distortion is deliberately large. The principle of the Hill lens was extended by Zeiss in the Pleon and Sphaerogon lenses patented about 1935. The Elgeet Company has recently introduced a 13 mm. f 1·5 reversed telephoto lens for 16 mm. cameras.

Recent Developments. The post-war years have seen great activity in photographic lens design, and possibly the most important reason for this is the introduction of new optical glasses. High-index glasses with low dispersion have been introduced, the use of which enables flatter curves to be employed on the lens surfaces, with reduced zonal spherical aberration and astigmatism.

No fundamentally new design has been introduced, but improved developments have been made of most of the already existing types. Successors of the triplet construction with a meniscus element in the front air space (originally due to Ernemann) include the Kodak Cine Ektar f 1·9 lenses and the Kern Switar and Pizar lenses of f 1·4. From the quadruplet design the following lenses have evolved: the Wray Lustrar f 4·5; the Summarit f 1·5 and Summarex f 1·5 for the Leica camera; the Taylor-Hobson Amotal f 2 for the Foton camera and the Ivotal f 1·4 for 16 mm. cinematography; the Dallmeyer Septac f 1·5; the Kodak Aero Ektars f 2·5; the Ross Xtralux f 2; the Wray Unilite f 2 and Cine Unilite f 1·9 and f 1·0 copying lens. An f 0·71 lens of unusual form with a very short back focus has also been produced.

Performance of the Petzval type has been improved by the use of crown glass of high index, and there has been a revival of the use with this lens of a negative component close to the focal plane to correct field curvature in a 2 ins. f 1·5 projection lens, by Schade, to cover 14°. This arrangement was originally used by Piazzi Smyth in 1866.

Aspheric Lenses. The advantage of using a non-spherical refracting surface, to correct aberration in a lens system, has been known since the seventeenth century. However, in the succeeding two centuries this advantage was hardly exploited, since little was understood as regards the aberration of optical systems and furthermore the ability to manufacture such surfaces was not developed.

In the early part of the present century, however, interest was renewed as the photographic lens, using conventional spherical surfaces, underwent significant development.

Between 1908 and 1922 Carl Zeiss took out several patents with respect to both the design and manufacture of lenses using aspheric surfaces. Earlier attempts by Zeiss to manufacture aspherics were mainly concerned with the moulding of components rather than the then almost traditional hand figuring methods.

The full significance of the use of aspheric surfaces, other than conic-sections, was demonstrated when Berthardt Schmidt introduced the system that now bears his name.

Like many previous steps forward his invention was of a simple nature but it opened up a whole new line of thinking to the photographic art. Schmidt's discovery comprised of only a thin aspheric corrector plate and a spherical mirror but the essence of his discovery lay in the positioning of the corrector plate relative to the mirror such that it contributed to both the axial and oblique aberration corrections.

Stemming from this discovery have come many modifications including the Dioptric Schmidt type of system which replaces the spherical mirror by a more conventional refracting member. Such derivatives have yielded lenses of very high relative apertures of f 0·7, covering substantial fields of view.

Since the end of the 1950s manufacturing techniques developed to provide surfaces of larger deviations of figure than the earlier corrector plates, whilst achieving an accuracy of figure equal to that of more conventional spherical surfaces. As a result the aspheric surface can either be used to simplify an existing type of construction yet yield an equivalent performance, or such a surface may enable the optical designer to achieve a result hitherto difficult to obtain by using spherical surfaces only.

CC-0. Agamirsam Digital Preservation Foundation India

Examples include the 12 mm. *f* 1·2 Elgeet Golden Navitar and the 5·8 mm. Kinoptic lens for the 16 mm. format. For the 35 mm. cine format the 18 mm. and 25 mm. *f* 2·0 Cooke Speed Panchro Series III lenses both have an aspheric components, as have the Varotal III and Varotal V 10 : 1 zoom lenses for television cameras.

Zoom Lenses. The scale of the picture taken with a camera depends upon the focal length of the lens used; from a given viewpoint to photograph a particular object at different magnifications necessitates the use of different lenses. In cinematography a need arose for a lens of continuously variable focal length, within certain limits, so that close-ups could be taken, the image remaining sharply focused on the film as its size was altered. Projection lenses of variable power were described as early as 1902, but taking lenses of this class seem to have been developed from 1930 onwards. The earliest of these included the Bell and Howell Cooke Varo, the Busch Vario-Glaukar and the Astro Transfokator. The latter was an afocal zoom attachment intended to be used in front of the normal motion-picture lens. These lenses represent the first known deliberately designed zoom lenses and in every case some kind of cam was used (i.e. mechanical compensation) to hold the image in constant focus while the focal length was being changed.

Due possibly to the economic conditions of the film industry in the 1930s, activity in the design of zoom lenses subsided until 1946, when F. G. Back introduced the Zoomar lens for 16 mm. cameras. This lens involved a succession of positive components in which the alternate second and fourth components were coupled together and moved linearly along the lens axis to vary focal length. Such a system yielded an approximation to a constant image plane position during change of focal length (optical compensation).

Zoom lens design developed rapidly since then and currently zoom lenses are available for microscopy, cine and still photography, television and telescopic applications. The economic advantages of optical compensated zooms against the performance advantages of mechanically compensated zooms has in the past tended to cause manufacturers to produce only one type or the other dependent on their type of market. However, current trends involving a wider specification on range of focal lengths and aperture suggest that the mechanically compensated zoom holds the better promise for future development.

The majority of current optically compensated zoom lenses achieve a maximum focal length to minimum focal length ratio of about 4 : 1, but the Zoomar Company also introduced a lens having a 7 : 1 ratio for television cameras. In 1950 H. H. Hopkins described a mechanically compensated zoom lens having a 5 : 1 ratio whilst in 1960 Rank Taylor Hobson introduced the Varotal III zoom lens involving three moving members having a focal range of 10 : 1 in two 5 : 1 steps. The changeover from one focal range to the other being achieved by a fourth moving member occupying one of two positions.

Since 1960 focal ratios extended even further with the introduction of mechanically compensated zoom lenses for cine and television by Angenieux and Rank Taylor Hobson having continuous ratios of 10 : 1. Such lenses are optically very complex and required intense development of their associated mechanics. However, today such zoom lenses are attaining a level of performance equivalent to the range of fixed focal length lenses they are intended to replace. Generally at least two components of the lens system are moved in relation to the focal plane and to each other, and precision cams giving non-linear axial movements are necessary.

Mirror Lenses. A disadvantage of the orthodox lens with refracting elements—a dioptric system—is that colour correction is never perfect, there being always a residual secondary spectrum. The attraction of an all-reflecting (catoptric) system with its complete freedom from chromatic aberration is therefore obvious, particularly in the utilization of actinic ultraviolet radiation or in extending the sensitivity of the emulsion to the infra-red. Whilst mirror-lens combinations had been used previously, the arrangement used by Schmidt in 1931 was probably the first successful photographic lens of this type. Coma and astigmatism of the spherical mirror were eliminated over a curved field by placing a stop at the centre of curvature, and spherical aberration was corrected by a plate of suitable aspheric form in the plane of the stop. The system is strictly catadioptric, since refraction occurs at the correcting plate, but even so, chromatic aberration is negligible. A relative aperture greater than *f* 1·0 was obtained, but the field was steeply curved.

The aspheric correcting plate was replaced by Gabor with a meniscus element using spherical surfaces, and independently by Bouwers and Maksutov with a concentric or near-concentric meniscus of appreciable thickness. An achromatized corrector consisting of a meniscus plate and a doublet aspheric plate has been proposed by Linfoot and Hawkins, on the grounds of greatly improved definition, whilst Wynne has suggested a double meniscus corrector.

The main application of the Schmidt lens and its developments has been in astronomy, where extremely high apertures are required. For X-ray fluorography, a Danish firm has made a 4 ins. *f* 0·75 for 35 mm. film and a 6 ins. *f* 0·85 for 70 mm. film. The lens has also been used for television projection, the curved end of the cathode-ray tube matching the curved field of the lens. Aspheric correcting

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

plates of moulded gelatin have been described.

Ultra-Wide Aperture Photographic Systems. In general such systems fall into one of two types. They are either the derivatives of the Schmidt system (reflecting or dioptric); or extensions of the double Gaussian, Triplet or Petzval types. The advantages in the choice of any system evolves round the field coverage requirement and whether the image plane need be flat.

Mirror Schmidt systems of apertures around *f* 0·7 have been used extensively in television projection, whilst the Dioptric Schmidt has found a major application in cine radiography work. The advantage here lies in the fact that the focal plane lies external to the lens and does not vignet a central area of the lens aperture as in the mirror Schmidt system. The focal plane is still curved but in the opposite direction to the classical Schmidt and the film is curved to suit. Examples from the patent literature by Warmisham and Wreathall show apertures of *f* 1·0 covering 32° of field and *f* 0·7 covering 22½° of field.

Derivatives from the Double Gaussian, Triple and Petzval types of construction have found application in cine photography, cine radiography and cine projection. The two former types yield essentially a flat field but of reduced angle compared with the dioptric Schmidt.

Examples for 16 mm. cine include *f* 0·95 lenses by Angenieux and S. O. M. Berthiot, these being basically extended Double Gaussian systems. Triplet derivatives include an *f* 0·75 covering a 14° field by Schade and the *f* 0·519 lens by Yoshido, the latter using an aspheric surface to achieve the extreme aperture. Kaprelian has shown an example of an extended Petzval type of construction having a relative aperture of *f* 0·7 covering a field of 34°.

Non-Reflecting Films. At every air-glass surface of a refracting lens system approximately 5 per cent of the light incident there is reflected; the precise amount depends on the refractive index of the glass (and on the degree of polish and cleanness of the surface). In a complicated system, therefore, as much as 50 per cent of the incident light may be reflected backwards and forwards between the surfaces, a good proportion finally emerging and spreading over the image plane. The light transmission of the lens is thus reduced, and from the point of view of speed its rated *f*-number is incorrect: for an unbloomed lens of eight air-glass surfaces the effect is equal to approximately half a stop. For this reason it has been proposed that aperture markings should be photometrically calibrated, and some manufacturers are, in fact, engraving "T-numbers" on their lenses. The effect of the non-image forming light falling on the focal plane may be more serious than the fall in transmission, however, because the contrast of the image may be seriously reduced.

H. D. Taylor in 1892 first recorded that the surface reflection at an air-glass surface was reduced if the surface had become naturally bloomed by atmospheric action. For light of a given wavelength, if a layer of a suitable refracting material is deposited on the surface with a thickness of one-quarter wavelength, destructive interference occurs between light reflected at the air-film, film-glass surfaces and the amount of light reflected is reduced. Ideally, the refractive index of the film, for the wavelength considered, is equal to the square root of that of the glass on which it is deposited. Magnesium fluoride has a suitable refractive index, the value for the helium *d* line being 1·390. This substance is deposited by vacuum evaporation to the requisite thickness. The process is most commonly employed for the production of non-reflecting films, and was first described by Cartwright in 1939.

For white light, the film thickness cannot be ideally correct for all wavelengths and a compromise is adopted; as an average value, reflected light is reduced to 1 per cent per surface. With a complex photographic lens the increase in light transmission is appreciable, and a bloomed lens of eight air-glass surfaces is only about one-quarter stop slower than an ideal lens of the rated *f*-number (compared with one-half stop for an unbloomed lens of similar construction). The increase in contrast, due to the reduction in reflected light, is quite considerable.

Anamorphotic Systems. In general, within the limits set by any inherent distortion, the photographic lens forms an image geometrically similar to the object. Trapezoidal distortion can, of course, be introduced by a suitable tilt of the plane of the photographic plate or film and of the screen of an enlarger. Descriptions of optical systems which will deliberately distort the object by giving different magnifications in two mutually perpendicular meridians date back for a hundred years. Brewster's teinoscope consisted of a refracting prism system, whilst G. Chrétien proposed the use of cylindrical lenses in three-colour photography, and combinations of cylindrical reflecting and refracting surfaces have been suggested.

Apart from its application to comic pictures, anamorphosis has been little used in photography up to recent times; with the advent of wide-screen cinematography, however, there has been a revived interest. With an anamorphic attachment fitted to the taking lens, a scene of approximately twice the usual width is compressed into the standard film width, whilst there is little change in the vertical direction; on projection, a similar attachment expands the picture in width to fill the wide screen. A refracting prism system of the Brewster type has been developed by Taylor, Taylor & Hobson; the Delrama anamorph of De Oude Delft is a reflecting system employing a spherical and a cylindrical mirror. K.J.H. (P.A.M.)

LENS HOOD. Shield fitted to prevent rays of light from outside the picture area from falling on the lens. Although outside the angle of view of the lens do not affect the sensitive surface directly, they set up internal reflections in the lens and may cause ghost images and a general degradation of the contrast of the negative.

There is no need to use a lens hood with the sort of box cameras which have the lens set well back into the body—often behind the diaphragm—but a hood is almost a necessity on the more expensive cameras with wide aperture lenses which are usually without any protection from stray light.

The simplest type of lens hood is no more than a short piece of tube, blackened on the inside to reduce surface reflections. It is made to slip directly on to the rim of the lens or filter mount. Some cameras have a screw fitting.

Most lens hoods are made funnel-shaped with the object of providing a relatively deep hood without cutting off the corners. The angle of the funnel conforms more or less to the angle of view of a lens of normal focal length. With this shape of hood there is always a risk of unwanted reflections from the inside surface if it is at all smooth or bright. The cheaper hoods of this sort are painted with dead black paint; in the more expensive types there are fine ridges machined on the inside surface to reduce reflections still further.

The most efficient hoods are those which conform to the shape of a square or round box with an aperture cut on the side opposite the lens. With this sort of shape there is no risk of internal reflection as none of the surfaces is so inclined that it can reflect incoming light rays on to the front of the lens. The aperture of the hood should, ideally, be of the same proportions as the negative; it should also be as small as possible without actually obstructing the angle of view of the lens (the distance between the lens and the hood aperture will govern this). Unfortunately, such hoods cannot be used with lenses which have front cell focusing unless the hood is put on after focusing.

Most lens hoods for hand and miniature cameras are of rigid metal construction; a few are collapsible. Larger hoods for studio and field cameras are often in the form of a rectangular bellows which can be extended to the limit where it starts to cut off the corners of the image on the focusing screen.

LENS HOODS. **Top:** *The main purpose of the hood is to shield the lens from light sources outside the picture area, which might otherwise cause reflections inside the lens.* **Bottom:** *For maximum efficiency the hood should cut down the cone of light accepted by the lens so that it just covers the negative size.*

When choosing a lens hood for a camera with a rising front, it is important to check it for cut-off with the front raised to the limit. A hood which just fails to cut the corners of the image with the lens central will cut off the bottom corners when the front is raised.

The shorter the focal length of the lens, the shallower the hood that can be used with it. Telephoto lenses, because of their narrow angle of view, can be fitted with very deep and efficient hoods which are a great help in producing a brilliant, fog-free image.

LENS, INTERCHANGEABLE

Lens system fitted into a camera (or projector or enlarger) in such a way as to be easily removable and changed against alternative lenses of different focal length or aperture. The use of interchangeable lenses extends the scope of a camera; such lens systems are widely used in better-class cine, miniature and reflex cameras as well as in many professional camera types. On many cine cameras variable focus (zoom) lenses serve the same function without the need for lens changing.

Optical Considerations. Alternative focal lengths provide a range of angles of view and image scales. They are frequently specified in relation to the normal focal length of the lens for a given picture format. This is accepted as being approximately the same as the diagonal of the picture format. Thus the diagonal of a theoretical 24 × 36 mm. format (in practice the image produced on the film is often slightly smaller) would be about 43 mm.; usually the normal focal length for a miniature camera is

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

INTERCHANGEABLE LENSES. Certain cameras, notably precision models taking 24 × 36 mm. negatives, often take a whole series of interchangeable lenses of various focal lengths to cover a range of image angles. A typical series may include lenses from 3·5 or 4 cm. wide-angle to 40 or 50 cm. telephoto units with angles from around 60° down to 5°.

45 or 50 mm. The diagonal angle of view when the focal length is the same as the image diagonal is about 53°. The normal (or "standard") focal lengths for different image sizes are shown in a table below:

STANDARD FOCAL LENGTHS

Nominal Image Format mm.	ins.	Diagonal mm.	Normal Focal Length mm.	ins.
8 × 11		13·6	15	⅝
10 × 14		17·2	17–20	⅝–¾
12 × 17		20·8	20–25	¾–1
18 × 24	¾ × 1	30	30	1¼
24 × 24	1 × 1	34	35–40	1⅜–1⅝
24 × 36	1 × 1½	43	45–50	1¾–2
28 × 40	1⅛ × 1⅝	49	50	2
cm.				
4 × 4	1⅝ × 1⅝	56·5	55–60	2¼–2⅜
4.5 × 6	1¾ × 2¼	73 }		
4 × 6·5	1⅝ × 2½	76 }	75	3
6 × 6	2¼ × 2¼	81	75–80	3–3¼
6 × 9	2¼ × 3½	100	100–110	4–4¼
9 × 12	4 × 5	150	150	6
12 × 16	4¾ × 6½	200	200	8
13 × 18	5 × 7	225	200–250	8–10
10 × 21	6½ × 8¼	265	250–300	10–12
18 × 24	7 × 9½	300	300	12
20 × 25	8 × 10	320	300–380	12–15

Lenses of shorter focal length, yielding a wider angle of view, are generally referred to as wide-angle lenses; longer focal lengths are long focus or telephoto lenses. (The two terms are used interchangeably. Strictly speaking there is a difference in the optical construction—though not in the use.)

The shorter the focal length of a lens, the smaller the scale of the image taken in, but the wider the field covered. A wide angle lens is thus useful for taking in a large view in confined quarters where it is not possible to get far enough away from the subject to include it all with a normal lens. The image usually shows an enhanced perspective effect, because the wide view tends to take in a considerable portion of foreground, and such foreground objects loom large in the picture compared to the more distant ones.

The longer the focal length, the larger the image scale but the smaller the view covered. Long-focus and tele lenses therefore are useful for showing up detail of distant objects on a large scale. The perspective in long focus views appears subdued, largely because such a view frequently takes in only a small image field of objects situated at a distance where there is less graduation in depth. In fact, the perspective depends only on the camera view point and from a given viewpoint the geometrical perspective of any portion of the image taken in by a wide-angle normal and long-focus lens is identical but the apparent perspective in viewing the print is dependent on the viewing distance.

Short focus lenses yield a considerably greater depth of field at any given subject distance and lens aperture than long focus lenses. The depth of focus, at a given relative aperture, is however the same. When related to the image scale (magnification or reduction) a depth of field, however, is also constant irrespective of the focal length. That is to say, the depth of field for a subject taken with a long-focus lens is the same as the depth for the same subject taken with a shorter focus lens at a sufficiently closer distance to reproduce the subject in the same scale on the film.

While a normal or even wide-angle lens for a given picture format can be used as a long-focus lens for a smaller format, the reverse is not practical. This is because a wide-angle lens must be designed with a suitable covering power to cover the field of the image format with which it is used. A normal lens for a given format is not usually able to cover the wider field required of a wide-angle lens for a larger format, even though both may be the same focal length.

Wide angle lenses for reflex cameras are also subject to design limitations posed by the need for an adequate back focus to clear the reflex mirror. This calls for inverted telephoto type constructions.

Convertible and Interchangeable Lenses. There are three main ways (apart from zoom lenses) of providing alternative focal lengths for a camera:

(1) By changing the whole lens;
(2) By changing part of the lens;

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LENS CHANGING SYSTEMS. 1. Standard screw-in mount. 2. Bayonet mount in focal plane shutter camera. 3. Bayonet mount holding lens in front of diaphragm shutter. 4. Bayonet mount of convertible lens system (with rear lens component built in behind the shutter). 5. Interchangeable lens mount with retaining ring. 6. Interchangeable twin-lens panel.

(3) By fitting lens attachments in front of the fixed lens of the camera.

Fully interchangeable lenses are invariably mounted in front of the camera shutter. With focal plane shutter cameras this presents no problem, since the shutter itself is well behind the lens. The range of focal lengths available for such a camera is usually limited only by the physical dimensions of the camera mount and by considerations of usefulness. Angles of view may range from nearly 180° to 1 or 2°, focal lengths (with for instance a 35 mm. miniature camera) from 8 or 10 mm. (fish-eye lenses) to several metres.

Practical ranges found on professional cameras often go from 20 to 1,000 mm.; for amateur use about 28 to 200 mm. is adequate.

With diaphragm shutter cameras the construction becomes a little more complicated. Here the interchangeable lens range needs a reasonable constant back focus to avoid vignetting if the diaphragm shutter is too far behind the rear of the lens. Focal lengths are thus more limited, but again is nearly always adequate for amateur use. The limitation is given by the minimum back focus to enable the lens to fit in front of the shutter (for wide-angle lenses) and by the dimensions of the shutter (for long-focus lenses).

An alternative, with diaphragm shutters, is to change the lens together with the shutter. This requires a separate shutter for each focal length, but is frequently used with professional and technical cameras.

In a convertible lens system for alternative focal lengths part of the lens—the rear element or elements—remain fixed in the camera, while only the front units are interchanged. The different front units together with the fixed rear component then yield the alternative focal lengths. The rear unit is mostly mounted behind the shutter, a diaphragm-type built into the camera.

This particular type of interchangeable lens system is nowadays only used on a few 35 mm. miniature cameras; it is somewhat

CONVERTIBLE LENS SYSTEM. The rear elements of the standard lens (top) are permanently built into the camera—usually with the shutter—but the front element is interchangeable. Alternative front elements can be combined with the rear components to produce a wide angle or telephoto lens system or even a lens unit permanently focused on a given close-up distance, for instance for same-size copying.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

limited in the range of focal lengths available (usually in a ratio of 1 : 3), and also poses special design problems.

The design problems with convertible lenses of this kind are considerable, and both the wide angle and the tele constructions are usually considerably more complex than they would be with a fully interchangeable lens of similar focal length.

More old-fashioned types of convertible lens for field cameras consist of two components or groups of elements which can be used either singly or together to give different focal lengths.

A related design idea is the use of afocal lens attachments which fit in front of the complete (and firmly built-in) camera lens to convert the latter into a wide-angle or tele lens unit. Such conversion attachments have been produced for a number of cheaper miniature cameras, as well as for twin-lens reflexes where changing both the finder and the taking lens is not always practical. In the simpler versions they sometimes involve certain quality compromises, since it is not easy to design a camera lens so that it gives optimum performance on its own as well as in combination with the lens attachment.

Lens Changing Mounts. The commonest ways of changing lenses is by a bayonet or by a screw mount. With a screw mount the whole lens screws in and out of a fitted flange in front of the camera. Changing of screw-mounted lenses tends to be slow, but wear and tear is evenly distributed over a large area of screw thread, so that screw mounts remain reliable for a long time.

AFOCAL ATTACHMENTS. Where the camera lens is fixed, alternative focal lengths are sometimes obtainable by placing magnifying or reducing attachments in front of the camera lens. This system is used for some twin-lens reflex models where for instance a wide angle attachment (top) can convert a 75 mm. camera lens into an effective 52 mm. one, while a tele attachment (bottom) can increase the focal length to around 115 mm.

With a bayonet mount the lens can be clipped into and out of the camera by approximately a quarter turn, and is generally secured by an additional catch. Lens changing is much more rapid, but the mechanical bearing surfaces are smaller and thus subject to more intense wear. It is less easy to seat a lens absolutely firmly with a bayonet mount.

Various combined screw and bayonet mounting systems have been tried at different times in an attempt to utilize the advantages of both systems. Systems with bayonet or screw clamping and retaining rings also exist. Convertible lenses (with interchangeable front components) are almost invariably bayonet mounted; so are interchangeable lenses for cameras with a built-in diaphragm shutter.

On technical and certain other cameras where the lenses change together with the shutter, lens and shutter are usually mounted on a panel which is clamped in position on the front unit of the camera.

Afocal attachments may screw or bayonet into the front mount of the normal camera lens.

With still cameras screw and bayonet mounts exist in a variety of sizes and specifications, and the camera will usually take only the lenses of a series specially designed for it. With cine cameras there is greater uniformity through the use of standard mounts: type D for 8 mm. cameras and type C for 16 mm. cameras. These are screw mounts, in which the thread, pitch, and the flange-to-film plane distance are accurately specified.

For rapid lens changing cine cameras often carry two or three focal lengths on a lens turret. Rotation of the turret brings the alternative focal lengths into place in front of the film. Turret cine cameras are however giving way to an increasing extent to cine cameras with zoom lenses. Turret systems have also been tried with still cameras, but have not been successful owing to the great bulk of a turret with two or three lenses.

A special kind of interchangeable lens mount is the sub-assembly mount where the camera takes one or more interchangeable units consisting of a focusing mount and aperture controls. The lenses themselves then fit interchangeably into this sub-assembly mount. The advantage is less bulky interchangeable lenses, since the latter consist only of the lens unit proper without a separate focusing mount for each focal length.

Rangefinder and Exposure Meter Coupling. Cameras in which the image is focused on a ground glass screen (technical and reflex models) need no special focusing provisions for the different focal lengths. Where the same focusing mount or focusing scale is used for different focal lengths, the distance figures are

however not correct for all of them. Full interchangeable lenses on rangefinder cameras usually carry a differential coupling which moves the rangefinder mechanism through the same distance corresponding to a given focus change of the lens. Thus long focus lenses, which require an appreciable focusing travel for setting to nearer distances, still work correctly with a built-in camera rangefinder.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

The same arrangement is not always possible with convertible lenses, since the focusing movement is also built into the camera and remains constant. A given focusing travel (extension of the front lens unit) thus corresponds to different distance settings according to the focal length of the lens. For that reason convertible lens systems have fallen largely out of use with rangefinder cameras; rangefinder focusing there involves focusing with the rangefinder in the normal way, reading off a distance figure on the standard distance scale and resetting the focusing mount to a corresponding distance figure on another scale.

Exposure coupling—with cameras having built-in semi-automatic or automatic exposure meters—is however easier with a convertible lens system. There the shutter is firmly built into the camera and is easily linked with the iris diaphragm of the lens (sometimes even the iris is built into the camera). The same applies to interchangeable lenses that fit into the front of a shutter built into the camera. The coupling there usually takes place via some system of preselector diaphragm controlled by the exposure meter or by the meter setting control.

Complete exposure coupling with cameras taking fully interchangeable lenses in front of a focal plane shutter is rare, since such cameras are not normally intended for the user who requires exposure automation. Exposure coupling with focal plane shutter cameras is mostly confined to coupling the shutter speed setting control with the exposure meter, the aperture being pre-set and pre-selected separately on the lens. On one or two cameras however the aperture control on the lens can also be linked with the exposure meter.

Exposure coupling problems with technical cameras rarely arise, as these cameras are not normally fitted with built-in exposure meters.

Viewfinders. Cameras other than single lens reflex and technical types need supplementary viewfinders and viewfinder adaptations to show the field of view taken in with the different focal lengths. Camera makers produce various types of multiple finder for this purpose; on many modern rangefinder cameras the viewfinder carries additional image frame lines to show the field of view with selected alternative focal lengths. For the very long focal lengths rangefinder cameras often use a reflex housing for accurate focusing and viewing. Twin-lens reflex cameras need no special viewing provision, as long as the alternative lenses (or lens attachments) are available in matched pairs to take the place of, or fit over, the finder lens as well as the taking lens.

Projectors and Enlargers. The lenses of slide projectors and often also cine projectors are interchangeable to provide alternative screen image sizes for a given projection distance, or alternative projection distances for a given screen size. The longer the focal length, the smaller the screen image size (other things being equal), or the longer the throw required for a given screen image size. Short focus projection lenses thus are useful when projecting in small rooms; long focus lenses are essential for large halls. The lenses are usually fitted in screw mounts or in sliding tubes.

Most enlargers—especially those taking a range of negative sizes—have interchangeable lenses. The changing mounts are usually screw threads, since speed of lens changing is of no importance. The focal lengths of enlarging lens used are usually slightly longer than the corresponding normal camera lenses, to ensure adequate coverage. The problem of alternative focal lengths for a single negative size rarely arises—except possibly for high degrees of reduction where a shorter focus lens (shorter than that normally used for a given negative size) permits a higher scale of reduction without excessive lens to negative distances. At such great extensions even a short focus lens will cover the negative area adequately. Multiformat enlargers sometimes carry two or even three lenses mounted on a turret or sliding mount for more convenient lens changing.

LENS MANUFACTURE

The manufacture of a photographic lens is the product of the combined skills of the mathematician who designs it and the craftsmen who fashion the lens elements and mounting.

There is probably no product which demands higher precision in all stages of design and production than a photographic lens and the industry is one in which the craftsman still holds a premier place.

For a lens system to be satisfactory for use as a photographic lens it should be free to a very high degree from chromatic and spherical aberrations, from coma, astigmatism, and distortion, and it should have a flat field so that it will produce a sharply defined image of a given object plane over the whole of the image plane it is intended to cover.

It is in practice impossible to eliminate all aberrations completely; the designer's task is to reduce them all simultaneously to the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

LENS MANUFACTURE. The precise operations and the way in which they are carried out vary from one lens manufacturer to another, and indeed from one lens design to the next. The sequence of the major steps does however follow this pattern: 1. Cutting of blocks of raw glass into plates for moulding. 2. Moulding the blanks. 3. Smoothing (rough grinding) the blanks. 4. Fine grinding the blanks (mounted together on a grinding tool). 5. Polishing. The polishing head is fitted with a pitch casting which carries engraved in it a series of grooves. These are filled with jeweller's rouge (a special form of iron oxide). 6. Testing curvature with test plate. The appearance of Newton's rings when the test plate is in contact with the lens surface indicates how accurately the surface is finished. 7. Centring lens for edging. 8. Edge grinding. 9. Blackening of edges. 10. Coating of surfaces. 11. Mounting lens units in mount. 12. Final testing. 13. Finished lens mounted in diaphragm shutter.

greatest extent possible. This task becomes progressively more difficult as the aperture of the lens is increased.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

To meet these requirements the designer has at his disposal about a hundred types of optical glass with varying refractive indices and dispersive characteristics from which he can make the lens elements which he combines to form photographic objectives. Each element can be made with an infinite range of radii and with thicknesses and separations which are only limited by practical considerations of weight and convenience. He has also to keep in mind when combining a number of elements that if his combination is disproportionately long with respect to its diameter the loss of light due to vignetting at the margin of his image may become serious.

Designing. The design of the lens thus presents a complex mathematical problem with many variables. The classical method of going about it used to be to work out the general form of a lens from known principles, using logarithms and slide rules, followed by laborious ray tracing and subsequent modifications. Even when done with calculating machines, this ray tracing frequently involved many months of work before the design of the lens could be finalized.

The modern way is to do the job with electronic computers. These permit both far more elaborate ray tracing systems and provide the required answer within hours instead of months. There it is possible to try out a considerable number of alternative specifications to arrive at the one which meets the requirements best.

Lens designs evolved in this way are nowadays frequently tested by instruments that show the performance of a lens in the form of contrast transfer functions, which can be read off directly from the face of a cathode ray tube.

Optical Glass. Optical glass differs from ordinary sheet glass or plate glass in two essential ways. Firstly it must be homogeneous throughout its thickness and free from internal strain, and secondly its ingredients must be very carefully controlled so that the properties of the glass—e.g., its refractive index and dispersion—meet the requirements of the lens maker.

Optical glass is composed essentially of a very pure variety of sand specially chosen for its freedom from iron. This is mixed with one or more of a wide variety of metallic oxides chosen to give the glass the particular properties required. Lead oxide produces some flint glasses which generally have a relatively high refractive index and a high dispersion. Barium oxide gives a range of glasses having a low dispersion compared with their refractive index which are invaluable for producing lenses with anastigmatic flattening of the field. The mixture is melted in a fire clay crucible at a temperature of about 900° C. and constantly stirred until no further "gassing" occurs and all bubbles are removed. When the crucible cools down the glass tends to break up into pieces which are subsequently re-heated, pressed into plates and then annealed by being cooled down very slowly, over a matter of several days, to remove internal stresses. Some of the very modern and rarer types of optical glass are now melted in platinum crucibles and this results in purer and cleaner melts.

The resulting plates of optical glass are the materials which the lens maker works on for making his lens systems, which usually consist of not less than three and frequently as many as six or even seven separate glass elements. In most cases each of the elements is made of a different kind of optical glass.

If only a small number of lenses is to be made it is usual to cut up plates of glass, but where large numbers of a type are to be made it is more usual to use moulded blanks.

Plates of glass are cut up on a circular saw, the glass plate being held between vice jaws faced with hard wood pads, and fed up to the saw. The saw blade may be made of soft iron, about 10 to 12 ins. diameter with tiny diamond splinters embedded in the edge but diamond-bonded wheels are now more common.

After the glass has been cut into squares of a suitable size and thickness each piece is formed into a rough circle by shanking or nibbling off the corners with a crude tool known as a pair of shanks. The rough discs of glass so formed are then cemented together into a stick or roll and formed into a smooth cylinder either by rolling on a rotating flat steel plate with a mixture of emery powder and water, or by the more modern method of putting the roll through a centreless grinding machine. The circular blanks are then taken apart and are ready to be ground on their faces to the required curvature on each side. The circular blanks are now often cut from the plate by means of diamond-bonded trepanning tools.

Where large numbers of one type of lens are to be worked, this stage of the work is bypassed by the use of moulded blanks of the required diameter and having on them roughly the correct radii. These are supplied by the glass maker who makes them by cutting the original plates up into pieces of the necessary weight, reheating until they are sufficiently plastic to be pressed between iron tools of the required radius, and then reannealing. Mouldings naturally save the lens maker a good deal of work and waste less of the expensive optical glass.

Modern methods of continuous smelting of optical glass yield moulded blanks directly from the melt. Here the ingredients for the glass are fed continuously into one end of a platinum trough, and the glass passes through various temperature controlled stirring stages, to be tapped at the other end of the trough. The tapping takes place automatically, releasing a

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

drop of molten optical glass of pre-determined weight (controlled by the temperature and the viscosity of the glass). The glass drops drop into suitable moulds where they are pre-moulded into blanks, followed by annealing. This manufacturing procedure is virtually automatic, but is economical only when large numbers of similar blanks (batches of the order of 10,000 or over) are required. Frequently these blanks can pass directly to the grinding and polishing stage.

Roughing the Blanks. Until recently all these grinding operations were performed by presenting the glass disc by hand to iron tools ground to the required radius of curvature; if a convex surface was required it was ground on a concave tool and vice versa.

To-day the preliminary work of forming the curves is more often done on a spherical milling machine with a cup-shaped diamond-impregnated tool. The spindle carrying the tool is capable of being rotated over a considerable angle. When the axis of the tool is in line with that of the lens blank, a flat surface will be generated. If the axis of the tool is inclined at an angle to that of the lens blank, a spherical surface is generated on the glass, and as the angle between the two axes increases so the radius of curvature on the lens is shortened. The tool revolves at great speed and is supplied with a copious flow of liquid coolant, while the lens blank is rotated very slowly below it. A convex curve is produced by cutting with the inside edge of the cup wheel, and a concave curve with the outside edge.

After the required curves have been milled or "roughed" on the two faces, the lens blank is ready to be ground and polished.

Grinding. First, the lenses have a pad of pitch stuck on to one side. They are then held by hand and applied individually to a spherical tool similar to that used for hand roughing, and ground against the rotating tool with a medium grade of emery or carborundum powder in water.

Next the lenses are "blocked"—i.e., they are stuck by means of the pitch backing on to a spherical tool of suitable radius. The tool is heated, to melt the pitch and make it stick, and a number of lenses are fixed to it in this way and put through the subsequent stages of grinding and polishing at the same time. It is obvious that the number of lenses which can be worked at one time depends on the diameter and the deepness of curvature. A single lens with a deep curve approaching a hemisphere might have to be worked by itself, while the number of lenses with very shallow curves and plane surfaces that can be polished is limited only by the relative diameter of the lens to that of the tool.

The iron tools on which the grinding is done are first turned as accurately as possible to the required curve and then ground together in pairs, one convex and one concave and accurately measured from time to time on a spherometer—an instrument that measures the radius of curvature. The grinding process is adjusted until finally the tools have the required radius and a very fine finish.

The block of lenses is then screwed to a vertical spindle on which it can be slowly rotated. The iron tool oscillates over it and the block is fed in stages with successively finer grades of abrasive powder in water. After each grinding stage the block is thoroughly cleaned and examined to see that all the pits left by previous grindings with coarser abrasives have been removed. After the block has been finally cleaned from the finest grinding it is ready for polishing.

Polishing. The polishing is done on the same type of machine and in the same way as the grinding, but the polisher consists of a metal spherical tool coated with an even layer of pitch in which are cut grooves which retain the polishing medium—generally rouge (iron oxide) or cerium oxide. The pitch backing allows the lenses to "give" and so keep in intimate contact with the polisher.

As polishing proceeds, the lenses are examined from time to time to see that the action is even over the surface of the block. If it is found that the edges are polishing faster than the centre, the stroke of the arm carrying the polisher is shortened so that more work is put on to the central area, and vice versa. Sometimes the grooves in the polisher are widened at some particular zone for a similar reason. From this it can be seen that the polishing of lenses to a high degree of precision is very skilled work needing true craftsmanship.

The time for polishing varies considerably according to a number of considerations—e.g., the size of the block and the working temperature. Polishing is preferably carried out in an air-conditioned room, free from dust and at a set even temperature. Two to three hours is a reasonable time for a block of about six to eight inches diameter.

Checking. The block of lenses is passed as satisfactory when examination by a powerful magnifying glass shows that all traces of greyness have disappeared, and when it appears truly spherical and of the correct radius when a test plate is applied.

The test plate consists of a glass or quartz block polished flat on one side and with the required radius of curvature accurately polished on the other. Test plates are always made in pairs, concave and convex, ground and polished together, and tested from time to time during manufacture on a very accurate spherometer.

To use the test plate, both it and the lens to which it is to be applied are carefully cleaned to remove all surface grease and dust, and then placed in contact. When the surfaces in contact are viewed by a monochromatic light source—e.g., from a sodium lamp—any lack

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of perfect contact between them is seen as a pattern of light and dark bands, each dark band representing a separation between the glass surfaces of one half a wavelength of the light employed—about ·0003 mm. For a surface to be considered good enough for a good photographic lens not more than three such bands are tolerated, from which it will be appreciated that the spherical surfaces are accurate to a very high degree indeed.

Edging. When a lens has been finally polished on both sides it is edged. This consists of grinding the edge of the lens to the specified diameter, at the same time ensuring that the mechanical axis of the lens coincides with the optical axis. The optical axis is the imaginary line joining the centres of the two spheres of which the curved surfaces of the lens are parts. A photographic lens consists of a series of elements, each of which must be truly mounted about a common optical axis. The performance of the lens must be symmetrical about the axis, and this only occurs if all the elements are themselves truly centred on it. So the operation of edging is highly important and must be performed with the utmost care and precision.

The edging is done by first cementing the lens to an accurately made brass ring chuck which is then revolved slowly. As it turns, the operator observes the image of a small light source such as a lamp filament reflected on the surface of the lens. If the image moves, the operator alters the position of the lens by small transverse movements on the chuck. (The cement is previously softened by heating in a gas flame.) He continues to adjust the position by trial and error, until the images of the source, as seen by reflection at the back and front lens surfaces, remain stationary as the lens revolves.

The spindle, chuck and lens are then fitted into a grinding machine where the lens is slowly fed up to a rapidly revolving carborundum wheel or a copper lap impregnated with diamonds. Accurate adjustable stops on the machine determine the amount to be ground off the edge, and when the operation is complete the lens is removed from the chuck, and after cleaning is ready to be mounted.

Coating. Today nearly all photographic lenses have their surfaces coated or bloomed before being mounted. This process has the effect of increasing the light transmission of the lens and also of reducing the amount of light reflected back as stray light within the camera.

The material used for coating is magnesium fluoride. The lenses and the magnesium fluoride are placed in a vacuum chamber suitably separated. The chamber is then exhausted to a very high vacuum by means of a backing pump and an oil diffusion pump. The fluoride is then melted by an electric filament heater which causes it to evaporate and it condenses as a fine film on the lens surfaces. The thickness of the coating is controlled by watching the reflection of a lamp on the lens surfaces. When the colour of the film indicates that the thickness is correct the current is cut off and the vacuum broken. A purple film gives maximum transmission in the yellow green of the visible spectrum.

Mounting. The lens elements are now ready for mounting. The mount itself has to be turned to high precision limits, and particular attention must be paid to the truth of all the screw threads. It is also important for each glass to be held securely but without any pressure which might produce distortion, especially with changes of temperature.

Great accuracy is needed in mounting the elements so that the separations are exactly as calculated by the designer and the position of the iris diaphragm relative to the elements is correct.

Testing. Testing is the last, but far from least important, stage in the production of lens.

There are several methods of testing. In one, an image of an illuminated test object is produced by the lens and carefully examined with a high power microscope. Another method consists of using the lens to project on a screen a greatly enlarged image of a test object and then studying the image in detail. Two types of error are looked for—symmetrical, which may be due to the design or the construction, and unsymmetrical, which arises from slight inaccuracies in making or mounting the lens elements. Photographic tests are also commonly used, as well as interferometric tests at the design stage. A.W.S.

LENS MOUNT. Metal housing which holds the assembly of glasses making up lenses. It may also house the iris diaphragms and may be incorporated in the construction of between-lens shutters. Lens mounts on some cameras are fixed and non-interchangeable.

There are five principal types of lens mount: standard, sunk, collapsible, between-lens shutter types and focusing mount. There are also several varieties of the last-named type.

On a standard mount, the flange screw is near the back of the lens barrel so that most of the lens projects from the front of the panel when it is screwed home. This type of mount is sometimes called an iris mount because it is convenient for the fitting and adjustment of the iris

CC-0. Adamjee Digital Preservation Foundation, Karachi

diaphragm. The standard type of mount allows the lens to be fitted to the camera by a bayonet mount. This permits quick lens changing, since only a quarter turn or half a turn is required to position the lens. Usually a catch secures the lens in position, and has to be pressed or disengaged before the lens can be removed or changed.

its length to the existing camera extension and is useful in keeping down the over-all dimensions of the camera. Lenses for stand and studio cameras usually have standard mounts.

On a sunk mount, the flange screw is placed as close to the front end of the lens barrel as possible, leaving only a narrow rim to take the lens hood or filters. This type of mount is fitted on reflex cameras; it looks neater and gives the lens better protection than the standard mount, but it calls for more camera extension. The iris diaphragm in this case is controlled by a rotating ring on the front of the mount.

A collapsible mount is simply a standard mount that allows the lens to be pushed back into the body of the camera when not in use. It forms a convenient way of providing the necessary camera extension for the short focus lenses of miniature cameras. The lens barrel can be locked in the forward working position by pulling it out and turning it to engage a bayonet catch. This type of mount may also incorporate the focusing mechanism.

The between-lens shutter mount is found on the majority of hand cameras. The lens components are actually fitted by the manufacturer so that in effect the lens is sunk into the shutter mechanism and the blades of the shutter and the leaves of the iris diaphragm lie between the front and back components.

All British lens mounts, unless otherwise stated, are screwed with R.P.S. standard threads:

STANDARD FLANGE THREADS

Screw Diameter	1·000	1·250	1·500	2·000	2·250	2·500	2·750
Threads per inch	24	24	24	24	24	24	24
Screw Diameter	3·000	3·500	4·000	4·500	5·000	6·000	
Threads per inch	24	12	12	12	12	12	

Mounts made on the Continent usually have metric threads.

Cine Camera Mounts. Most cine cameras have a standard screw mount and the lenses are usually interchangeable. Two widely used standard mounts are the Type C for 16 mm. cameras and the Type D for 8 mm. The Type C mount has a diameter of 25·4 mm. (1 in.) with thirty-two threads per in. and a flange-to-film distance of 17·5 mm. (0·69 in.). The Type D mount for 8 mm. cameras has a diameter of 15·8 mm. (0·632 in.) with again a pitch of thirty-two threads per in. and a distance of 12·3 mm. (0·484 in.) from the lens flange to the film. There are, however, also a number of non-standard mounts for specific cine cameras which can then be used only with the lenses designed for them.

Bayonet Mount. On a number of cameras, especially 35 mm. miniatures and roll film

Bayonet mounts are rarely standardized, partly because the flange-to-film distance tends to vary from camera to camera. So even when one lens fits the mount of another camera, there is no guarantee that the lens will be positioned at the correct lens-to-film distance. Sometimes different cameras using bayonet-mounted lenses by the same manufacturer deliberately have different "keys" to the bayonet mount to prevent a lens from being used on a camera other than that for which it has been designed and set.

On some 35 mm. rangefinder cameras the bayonet mount engages a mechanism which automatically changes the image frame of the viewfinder to match the focal length of the lens.

Focusing Mounts. In a focusing mount the lens barrel is mounted in a housing which is screwed or slotted to allow the lens to be focused by sliding or turning it in the mount. The most usual system is the helical mount which screws the lens in and out by means of a coarse screw thread.

Occasionally lenses may have a dual focusing mount with two (or even more) helical threads and separate lens tubes for each to give a greater range of lens-to-film distances. This is useful for extra close focusing and such macro mounts—available for certain miniature still and narrow-gauge cine cameras—permit focusing down to a few inches.

Filter Mounts. The front mount of a camera lens if frequently designed to hold filters securely. The simplest way is to finish the front mount with a plain rim which then takes push-on filter fittings. These are easy to attach or remove, but not very secure.

The majority of camera lenses carry a screw thread on the front for screw-in filters in various standard diameters. A few cameras have a bayonet front mount to take bayonet mounted filters which are quick to attach or remove, yet secure in position.

The front lens mount is equally intended for taking supplementary lenses in their appropriate mounts or fittings. F.P. (L.A.M.)

LENS PERFORMANCE. Any assessment of lens performance is an attempt to determine the faithfulness of the image forming process carried out by a lens, that is, the degree to which an image corresponds to a perfect two-dimensional projection of the object. This correspondence is never perfect because the image-forming process is limited by the diffraction of light at the finite apertures used. In considering the reproduction of images—and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the information contained in them—we have to deal with the shortcomings of the lens other than just the lens. However, this section will be concerned with the lens image forming properties only and will briefly indicate some of the methods used to assess performance.

Telescopes and Star Images. Although primarily concerned with photographic optics, the earliest assessment of lens performance was concerned with astronomical telescopes and the images of stars. Aberrations in the lens led to diffuse and complex images with the pure aberrations being characterized by distinctive light distributions in the image. An assessment of the state of correction was based on the percentage of the energy falling in successively larger circular areas of the image. This did not always correlate with the observed performance, an obvious exception being a comatic flare which is quite disturbing in any subjective test.

Interferometry. Interferometric tests of photographic lenses, as carried out on a Twyman-Green type interferometer, give the departure from a true sphere of the wavefront leaving the lens. If the wavefront is truly spherical, or deviates from a sphere by not more than a quarter of a wavelength, then the image as formed by the lens for that particular field angle and focal plane will be indistinguishable from the theortically best available.

However, not all lenses are well corrected and even well corrected lenses have aberrations when used off axis. It is then necessary to assess the possible performance of a lens from the more complex interferogram. A criterion that suggests itself is to determine the portion of the wavefront that lies within the aberration tolerance (Raleigh Tolerance of $\frac{1}{4}\lambda$), as clearly the light from this region forms the bright core of the image whereas the remaining wavefront region forms a diffuse patch. Attempts to correlate such a criterion with an assessment of performance derived from test chart images have not however proved to be very satisfactory. It is not possible to predict the resolution limit but only to confirm that the percentage area of the wavefront well corrected is to some extent proportional to the logarithm of the resolution limit.

Edge Gradient and Acutance. One approach involving the actual image formed by a lens considers the image of an edge between two regions of unequal illumination. For a perfect lens (this term implying diffraction limitations only) the image is an intensity curve which decreases monotonically and is of finite slope. The slope at the mean intensity is termed the edge gradient. In practice this gradient decreases as the lens aberration increases. The effect of this decrease of edge gradient is evident in the images of extended objects as blurred edges and a general unsharpness.

The practical measurement of the edge gradient requires a knowledge of the magnification of the image, as increased magnification will decrease the edge gradient in the same manner as increased aberration. With this precaution it is possible to compare the performance of lenses under equal conditions. This test does not have the same sensitivity to image degradation as other tests to be described or subjective assessments. One difficulty is that the eye and the receptor used in the physical measurement of the edge gradient do not respond in the same way to variations in light intensity.

A criterion taking this point into account is the acutance. A high acutance value indicates that the lens forms sharp images of edges but not necessarily good images of point sources. It implies that the image of a point source is compact without a halo of light about it. Thus a high acutance is not the same as a high resolution limit since a point image with a sharp centre spot and a diffuse halo (e.g. with spherical aberration) would give a high resolution limit but a low acutance value.

The acutance is more concerned with low spatial frequency detail, as implied in its use of an edge as object, and so is a quality criterion covering only a part of the workings range of a lens. If later components in the optical train restrict the spatial frequency range in use then the value in assessment of performance increases.

Resolution Limit. This is the limit of resolvable detail, as determined from test charts. The form of test charts is very variable, each generation correcting the faults of the previous one. Thus there has been a progression from multiline gratings to two-line Cobb charts, in an effort to eliminate spurious resolution, and a return to three or four-bar gratings. Gratings with continuously varying periods in the form of straight lines or sectors of a star have also been used.

However, most of the test charts used have been such that their images do not have the same form of intensity distribution as the object. This leads to difficulties in the measurement of the resolution limit due to the lack of resemblance. It further makes the decision of continued recognizability difficult and partially accounts for the variation of results between observers using the same test chart and for the greater divergence between the values obtained using different forms of chart.

The resolution limit criterion is also unsatisfactory in that the single-number performance figure derived is based solely on the high spatial frequency performance of the lens with no consideration at all given to the imaging properties at low spatial frequencies. This fault is made more serious by indications that it is the low spatial frequencies that are operative in any subjective assessment.

Transfer Functions. To overcome some of the above objections, lens designers now work with the optical transfer function. This function gives the ratio of the image contrast of a grating

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

EFFECT OF ABERRATION ON OPTICAL TRANSFER FUNCTION. A, transfer function curve for perfect lens. B, curve of lens defocused by 0·004 inch at f5. This already reduces the resolution limit to one-fifth of the value for a perfect lens. Reversal of contrast takes place in the region D. C, curve for lens with primary spherical aberration, partially corrected by a change of focus to give the same order of marginal aberration as in curve B.

of sinusoidal transparency to the object contrast as a function of spatial frequency. Sinusoidal here means that the transparency distribution of the grating from line to line follows the form of a sine wave. Spatial frequency is the reciprocal of the grating period expressed in lines per millimetre.

The spatial frequency Re, corresponding to the resolution limit of the lens as derived from classical theory, is given by

Re = 2 (Numerical Aperture)/Wavelength.

For an *f* 5 system Re = 400 lines/mm.

Two facts should be noted if this function is to be adopted for use in the assessment of lens performance. Firstly, any object, represented by a two dimensional incoherent intensity distribution, may be analysed into a set of Fourier terms. Each term of this set represents a sinusoidal transmission grating of a particular periodicity and may be transferred to the image plane using the optical transfer function where the set is reconstituted to form the final image. This procedure illustrates the use of a sinusoidal grating.

Secondly, whatever the form of the spread function formed by the lens, the sinusoidal grating will always be imaged as such a grating but with reduced contrast, possibly zero, and laterally shifted from the Gaussian image position.

It will be seen from the optical transfer function of a perfect lens that at all spatial frequencies above zero lines per millimetre the lens performance is impaired, a necessary condition imposed by diffraction at the edge of the lens opening. The aberrations in the lens reduce the optical transfer curve below the optimium. It is never possible for it to rise above the curve for the perfect lens.

Attempts have been made to derive a single figure of merit from such curves. An early attempt integrated the area under the curve and derived the equivalent band-pass, between zero spatial frequency and same value Re with unit contrast transfer, that would give the same integrated area. The upper spatial frequency limit Re is then taken as the figure of merit.

This method does not allow for the shape of the junction between the curves, so that several curves with equal integrated areas beneath them and, therefore, the same equivalent bandpass, appear to have equal performance when this is not so. Account must be taken of the relative importance of various spatial frequency regions and this is dependent on the receptor used in any final assessment and the spatial frequency spectrum of the object. If, however, an assessment is to be made of the lens alone, then the integrated square of the optical transfer function is a satisfactory assessment criterion.

All the above criteria can be measured for individual points in the image field only. If the assessment is to be applied to the whole image field then it is necessary to determine the mean of all the values representing individual points in the field. If some particular region in the field is considered of greater importance, for example the central region, it may be necessary to weight this region accordingly before determining the mean value of the performance figure for the whole image field. K.G.B.

LENS TESTING

The lens manufacturer uses highly specialized and very expensive equipment to make his own tests and in many instances he is more concerned with tests which assist him to maintain a consistently high standard of production rather than the tests which are of interest to the amateur user.

Before embarking on an extensive series of lens tests the average user must have a clear idea of the type of information he is likely to obtain.

He must understand that perfection cannot be expected from his lens and that performance will vary from one type of lens to another according to the type of work for which it was designed, its relative aperture and field of view and its cost.

An early understanding that some residual lens aberrations are theoretically inevitable will encourage him to concentrate on a search for the more obvious errors which may be caused by faulty manufacture, accidental damage or inaccuracies in mounting the lens on the camera.

The presence of different types of residual lens aberrations in different lenses means that

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

their relative performance can be expected to vary as the conditions of use are changed. Similarly, the performance of a motor car varies under different conditions of use. An attempt to assess either performance by a single figure of merit can be quite valueless and often misleading. Rather than rely on a lens assessment such as resolving power which requires expert knowledge, experience and elaborate equipment, it is preferable to allow a good lens to speak for itself in doing the type of work for which it was designed.

The visual and photographic tests described will assist the photographer to understand the limitations of his lens and suggest ways of minimizing their effects in practice.

The defects which are most likely to impair the sharpness and clarity of a photograph can be divided into two main categories. The first concerns the quality of the lens by itself and the second concerns the mechanical precision with which the lens and sensitive emulsion are positioned in the camera.

Whilst a qualitative test of the lens by itself requires special equipment together with some technical knowledge of photographic optics and experience in interpreting results, the user can conduct simple tests which will enable him to recognise lens errors and to see their effects.

Before testing for the presence of aberrations, second-hand lenses should be examined for gross errors arising from accidental damage or unskilled repair work.

Examine the metal components of the lens to see whether parts have been bent, screw thread and seating shoulders bruised or whether lens elements are loose in their cells. The lens elements of complex photographic lenses have to be centred about a common optical axis to an accuracy of a few ten-thousandths of an inch and quite small displacements are sufficient to spoil performance.

Centring Errors. The effects of centring errors on definition can be seen by using the lens at full aperture to form an image of a brightly illuminated pin-hole in an opaque metal sheet or card. The pin-hole must be placed as closely as possible to the axis of the lens, and, in the case of camera lenses, at a distance from the lens exceeding twelve times the focal length.

View the image on fine ground glass using a high-powered magnifier carefully focused on the greyed surface which should face the lens. As the lens is racked slightly inside and outside focus the image should remain circular in shape. If it shows an uneven shape with a flare to one side the lens is badly out of centre.

To make the test more critical make a lens holder which permits it to rotate smoothly about its own optical axis, maintaining focusing distance and a stationary image. Irregularities in the image due to lack of centring will be seen to rotate with the lens.

Mounting Errors. The performance of the best lens can be ruined by inaccurate mounting on the camera. The emulsion must be at the correct focusing distance from the lens, it must be flat and it must be at right angles to the optical axis of the lens. The precision of these mechanical settings must be increased as the quality of the lens is increased and as wider relative aperture reduces depth of focus.

TESTING FOR CENTRING. Examination of the image of a pinhole in the centre of the ground glass screen will show whether the lens is correctly centred. An image near the edges may also show up other faults. A, illuminated pinhole. B, ground glass screen. C, magnifier. D, image point with lens out of centre. E, astigmatism. F, coma.

A first class lens provides its best performance in one flat plane at right angles to its axis passing through the best focusing position on axis. The emulsion is placed in a cone of light proceeding from the lens aperture to an axial image point. In the absence of aberration the ideal point image of a point object will only be recorded when the emulsion is precisely at the tip of the cone. An emulsion in other positions will intersect the cone and finite circular areas known as discs of confusion will be recorded instead of points.

The angle of this cone is inversely proportional to *f*-number and the diameter of the disc of confusion will be the error of focusing divided by the *f*-number. Thus an error in focusing of ·004 in. with an *f* 2 lens produces a circle of confusion of ·002 in. A similar argument shows that squareness of the emulsion plane is equally important for image points out in the field of view.

It is dangerous to relate mounting errors too rigidly to depth of focus or depth of field. There

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is only one plane giving optimum performance and any departure from it yields inferior results. Depth of focus only indicates how far one can depart from the ideal before performance deteriorates to a standard previously selected by choice of an arbitrary circle of confusion.

Test Procedures. To carry out a test series set up a number of similar small test objects covering a range of intermediate object distances. Position one object at a distance from the camera corresponding to the focusing setting selected and position others at distances corresponding to the far and near distances given in depth of field tables and also at distances at, say, ½, 1, 1½ and 2 times the expected depth.

The objects should not obstruct one another, but it is desirable to group them as near the lens axis as possible so that all their images are clustered near the centre of the negative.

Photograph these objects at full aperture and check that the sharpest image corresponds to the object at the nominal distance. This checks the axial distance between lens and emulsion.

Now set up a series of objects in a flat plane, taking care that this plane is at right angles to the lens axis and positioned at the best distance for axial performance as determined by the previous test. The objects should be distributed over the complete field of view in some symmetrical pattern centred about the lens axis.

Photograph these objects at full aperture and check that any variation of image quality is distributed symmetrically around the axis of the lens. A variation of definition in different parts of the negative may be an indication of lens quality, but, if these variations are symmetrically disposed about the centre, the emulsion is likely to be flat and at right angles to the lens axis to a satisfactory degree.

Resolving Power. Although experienced interpretation of resolution does assist the manufacturer to attain a consistently high standard of production, it does not necessarily provide any simple and straightforward comparison between the quality of different lenses. Naturally, the manufacturer does make such comparisons, but the assessment of resolving power is only a part of this procedure and it takes a very extensive form covering assessment under a variety of conditions.

TESTING FOR OPTIMUM FOCUS. Layout of test objects (e.g., test charts) at various distances in front of camera. D, total depth of field at nominally focused distance.

TESTING FOR COVERAGE OVER FIELD. Layout of test charts over the field of the lens to check definition and compare the edges and corners of the field of view with the centre.

Resolution depends on a considerable number of factors. Apart from the magnitude of the residual lens aberrations, resolution depends on the conditions of test. It varies particularly with the layout of the test objects, the contrast of the object, the grain and sensitivity of the emulsion, exposure and development conditions and with the criteria adopted for focusing. In comparing two lenses, for example, it often happens that one appears to resolve better than the other when the object being photographed has detail of high contrast, whereas the second lens has a higher resolving power than the first when the contrast of the object is low. Similarly, it may happen that the lens which yields the higher resolving power is not the better for definition.

It is important to realize this difference between resolution and definition. Resolution is concerned solely with ability to record very fine detail whereas definition, or acutance as it is called in some quarters, is concerned with the sharpness or lack of "fuzz" at a boundary between larger areas of different density. In some lenses having appreciable aberration the best focusing position for maximum resolution is not necessarily the best for maximum definition.

The best way to test the performance of a lens and its mounting on the camera is to take a series of photographs of various types of subjects. A careful choice of subjects and conditions will give the amateur a much clearer and more satisfying indication of performance than any attempt to assess resolution by a test procedure which is necessarily complex, difficult to perform without experience, and liable to yield misleading results.

If photographs of different types of subjects show a consistent error and the lens appears to be in good condition, the camera should be tested to see whether the lens is badly mounted.

In those cameras which allow fine ground glass to be positioned in the focal plane,

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

LENS TESTING CHART. Chart for copying in natural size. A number of such charts laid out along the diagonals of the field of view covered by the lens will give some information about the covering power. Photographed at a distance of 10 feet, the medium group of lines marked M give images which with a 1 in. lens are 1/1200 in. wide, with a 2 ins. lens 1/600 in. and so on up to 1/150 in. with an 8 ins. lens. The clear spaces between the lines are the same width as the lines. The finer sets give lines with 1/2 and 1/3 of this separation, and the coarser sets have separations 1½, 2, and 2½ times that of the M set. The circular dots are the same diameter as the thickness of the medium lines. Charts should be made up which are both negative and positive copies of this chart and photographed under the same conditions. In the negative charts, especially those set up near the corners of the field, the images of the dots will, on examination with a powerful magnifier show up any coma flares, and spread due to lateral chromatic aberration.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

mounting errors may sometimes be discovered visually with the aid of a high-powered magnifier. In all cases, however, it is preferable to make tests photographically, especially with roll film cameras where the precise position taken up by the film is not well defined by the mechanical construction.

Spherical Aberration. This aberration concerns object and image points lying on the axis of the lens and takes its name from the fact that it must always be present in a lens made from a single piece of glass if its polished surfaces are spherical in shape. It refers to the way in which rays of light passing through the outermost annular zones of the aperture of a single lens converge to cross its axis nearer to the lens than do the rays passing through other zones nearer the centre.

To test for spherical aberration, set up the centring test described for centring errors taking care that the pin hole is bright enough to give sufficient light in the aberration fringes of the image and that the fringe is not lost by the effects of stray light falling on the ground glass. To give the maximum information about aberrations the pin hole should be as small as is consistent with enough light getting through to make all aspects of its image easily visible. Coloured fringes due to chromatic aberration should be removed by filters between lamp and pin hole. It is preferable to choose a filter transmitting light in the centre of the photographic spectrum, but change of filters can be used to assess variation of spherical aberration with colour.

The first impression of the presence of spherical aberration will be a vagueness about the position of best focus at full aperture. With a very well corrected lens the image comes into focus crisply, suddenly and definitely.

Next, stop the lens down by means of its iris and note whether the presence of spherical aberration is sufficient to change the position of best focus. Shift of focus on stopping down is present in a large variety of lenses and can amount to as much as 0·2 per cent of the focal length.

With the lens fixed in its best focusing position at full aperture, note the size and intensity of the aberration fringe round the image and see what changes occur on stopping down. If spherical aberration is corrected, the presence of residual zonal spherical aberration is likely to be most easily recognized when a relatively large but faint fringe is rapidly removed (well within one stop from full aperture) leaving a much smaller but brighter fringe which is removed at a slower rate on further stopping down. A lens which provides one large fringe which reduces steadily in size all the way down to small stops without any change of character may not be corrected at all for spherical aberration.

An interplay between two types of fringes is sometimes apparent in a corrected lens with zonal errors when the lens at full aperture is very slightly racked inside and outside the best focusing position.

Axial Chromatic Aberration. This is a failure of the lens to bring light rays of different wavelengths to a common focus. This can cause poor definition.

If the lens is intended for use throughout the visible spectrum, remove any filters before making a test. The effects of this aberration may be confused by any variation of spherical aberration with colour, but the appearance of the image should be in accordance with the best compromise correction for chromatic aberration over the whole lens aperture. This may show up in a corrected lens as a purplish or greenish fringe round the image. Blue fringes of importance photographically are difficult to see when using tungsten illumination deficient in blue light, and the eye and a photographic emulsion respond to different colours to varying degrees.

Find the best focusing position for a number of apertures, first in red light and then in blue light. If the focusing position, aperture for aperture, is always farther from or nearer to the lens in one colour compared with another, the correction of chromatic aberration may be suspected.

Astigmatism. This is an aberration affecting off-axis image points in such a way that the definition of a line image at one position in the field of view will vary according to the inclination of the line with respect to the centre of the field.

To test for astigmatism visually, arrange an illuminated pin hole as an object, and make provision whereby the pin hole, and thus its image, may be moved away from the axial position towards the edge of the field of view.

Take care that the pin hole moves in only one flat plane and that this plane and the ground glass are at right angles to the lens axis. Leave the focus set at the best position for the centre of the field and see how off-axis aberrations combine to give complex and irregular image patches as the pin hole is moved away from the axial position. The extent of the field of view that can be examined in this way will be limited by the effects of oblique illumination on to ground glass and by the construction of the magnifier, but it is possible to check that at all points equidistant from the lens axis the image has the same appearance. This symmetry of performance around the lens axis is another indication of a centred lens.

Astigmatism is rarely the only aberration present and the appearance of the image is complicated by the presence of field curvature, coma and transverse chromatic aberration. To test for astigmatism under these conditions, refocus the lens viewing a pin hole image well out in the field of view. Any tendency towards two distinct focusing positions, one giving minimum aberration fringes in one direc-

tion with respect to the lens axis and the other giving minimum fringes in a direction at right angles to the first may be recognized as the effect of astigmatism. The distance between these focusing positions is an approximate measure of the astigmatism that is present.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The confusing effects of coma may be removed in some cases by stopping the lens down, but it should be realized that, whilst the magnitude of astigmatism is the same at all stops, its apparent effect is smaller at small stops.

Repeat this test at different positions in the field of view and note whether there is a field position where astigmatism has been corrected.

Coma. This is another aberration concerning off-axis image points, and shows itself by the fact that a lens without any correction for coma reproduces object points as an unsymmetrical light patch flaring away to one side like the tail of a comet.

Comatic aberrations are usually of a complex nature and all that the average user can do is to examine the image at different points in the field and to notice the variations of the effects of coma at different positions and stops.

Curvature of Field. In the absence of all other aberrations, curvature of field will be an aberration which does not impair definition provided the sensitive emulsion can be placed on a surface which is curved (usually concave to the lens) to the extent demanded by this aberration. If a lens suffering from curvature of field is used with a flat emulsion definition will deteriorate steadily away from the centre of the field as the dimensional displacement of the emulsion from the ideal curved focal surface exceeds the depth of focus of the lens.

The test described above for astigmatism will show quite clearly the effects of curvature of field. If the ground glass has to be moved from the best focusing position on axis to achieve a better focusing position for a point well out in the field, then curvature is present. In some cases the way in which astigmatism and curvature are off-set against one another can be seen. In the case of anastigmat lenses try to find a position in the field of view where both these errors are absent.

Transverse Chromatic Aberration. This is a fault which causes the scale of the image to depend on the colour of the light and appears as a coloured fringe around the image.

In the above tests dealing with off-axis image points, any colour fringing extending along a line passing through the centre of the field will be due to this aberration. Since its extent and effects are the same at all apertures the confusing effects of other aberrations may be avoided by stopping the lens down to a sufficient degree. The presence of a complete spectrum of coloured images shows that this aberration is not corrected. Residual errors in a corrected lens, however, may show as purplish and greenish fringes on either side of the image.

Special Conditions. The tests described above should be adequate in the case of most lenses used on stills cameras, but cine lenses and miniature camera lenses present difficulties in connexion with short focal lengths yielding very high standards of definition on small negative areas. Although the ground glass and magnifier may be replaced by a microscope-viewing system of suitable numerical aperture, the mechanical difficulties will be too severe for most users and photographic testing is to be preferred.

The photographic tests for mounting errors described above may be used for this purpose if the test objects are chosen to show three types of definition. These are the definition of a point, the definition of a radial line or edge stretching out like a spoke from the centre of the field and the definition of a line running transversely across the radial lines like the rim of a wheel.

Test objects consisting of printed matter interspersed between radial and transverse lines are quite suitable for this purpose. A series of photographs taken at slightly different focusing positions and at different relative apertures, with and without colour filters, will suggest themselves to the user who has studied the visual tests described above.

Avoid the use of contrasty emulsions and contrasty developers which will hide important aberration fringes, and make certain that the test objects are evenly illuminated and square on to the camera.

Unless the user is experienced in the assessment of lens performance, he should not assume that the presence of aberration is an avoidable fault in the lens. The appearance of a visual image must be considered in conjunction with the power of the magnifier and any doubts should be checked by photographic tests on a correctly adjusted camera.

It is impossible to lay down any hard and fast

SINUSOIDAL TEST TARGETS. Top: *Template type transparent target. This oscillates in transfer function measuring instruments, so providing a sinusoidal density change of the image being scanned.* Bottom: *Sinusoidal target with continuously varying spatial frequency.*

rules concerning permissible amounts of aberrations. If a lens fails to give satisfaction when used for the purpose for which it was designed, it is best to refer to a reputable authority. Correction of faulty lenses should be left to the manufacturer who has the original design information and the correct tools and fixtures for such work. G.H.C.

Optical Transfer Function. This function is primarily concerned with describing the imaging properties of a lens in such a manner that these properties may be included with those of associated components in the imaging system to give the overall imaging performance. However, the function may be used to describe the lens performance alone.

The optical transfer function relates the ratio of image contrast to object contrast of a sinusoidally transparent grating as a function of the reciprocal of the period, termed spatial frequency, of such gratings. The function covers the complete spatial frequency range from zero lines per millimetre, for example, for a blank surface, to the classical resolution limit of the lens under test. The contrast ratio is normalized to unity at zero lines per millimetre, thus taking into account the photometric properties of the lens. Contrast is defined to be Michaelson contrast or visibility.

The sinusoidally transparent objects necessary for such an examination may take several forms. One of the earliest used is a series of apertures of sinusoidal form profile cut in an opaque sheet. If this is scanned by a slit the object is of the correct sinusoidal form with a d.c. bias. A series of such objects would be required to cover the complete spatial frequency range and frequently a set of such apertures of varying periodicity is placed on the periphery of an object drum. More than one period of each spatial frequency must be present to reduce errors in results obtained with such objects at higher spatial frequencies.

An alternative form of object is a sinusoidally transparent grating of continuously varying period. Such gratings may be produced by photographing a suitable cut out mask, of the form previously described, moved in the direction of the length of the lines during exposure, or by photographing the fringe pattern of a modified Michaelson interferometer.

Such an object grating, used for the measurement of the optical transfer function, is suitably illuminated from a white light source, and is moved continously in the object plane of the test lens. The image of the grating moves across the fixed scanning slit S. The light passing through the scanning slit is collected into a photo-detecter and the output from this is measured and possibly also continuously recorded.

OPTICAL TRANSFER FUNCTION MEASUREMENT. A, light source. B, grating. C, test lens. D, image of grating. E, scanning slit. F, photocell. G, recorded signal. The illuminated grating moves continuously in the object plane of the test lens so that the grating image moves across the fixed scanning slit. The light passing through the slit is collected by a photo detector and the output of the latter measured and if required continuously recorded.

The recorded signal will oscillate with the movement of the grating and the contrast in the image may be evaluated as a function of spatial frequency in the image plane of the lens.

If the object grating is of unit contrast for all spatial frequencies the contrast variation recorded as a function of spatial frequency is the required function. This requires a narrow scanning slit, its width being about one-tenth of the finest grating period it measures. The change of spatial frequency in the grating must also be slow to counteract the influence of one period of each spatial frequency only being present. With these conditions fulfilled it is possible to obtain the optical transfer function of a lens to sufficient accuracy. K.G.B.

LENTICULAR SYSTEM. Photographic process using a lenticular screen to break up an image into linear or area components which are subsequently recombined. The purpose of such splitting up is usually to accommodate two or more images interspersed in each other on the same area, Under some circumstances this greatly facilitates recording as compared with methods that record such images on separate sheets of sensitive material. Applications include a now obsolete system of colour photography, stereo photography, and image dissection for high-speed recording, etc.

Lenticular Screen. The main component of all lenticular systems is the lenticular screen itself, consisting of a transparent support embossed with a regular pattern of lens surfaces. Usually these are cylindrical running across the screen in one direction as strips. Nowadays such screens are usually made of plastic.

By embossing a second set of linear elements at right angles to the first, a truly lenticular screen—i.e. consisting of spherical lens elements—is obtained. The same effect is possible by combining two suitably matched screens at right angles.

CC-0. Panini Digital Preservation Foundation, Chandigarh

When this screen is placed in front of, and in contact with, the surface on which the camera lens projects an image, the individual lenticular elements break up the image into lines or points. They concentrate the elements into a smaller area, leaving spaces between them. Additional images can be recorded in these spaces by slightly displacing the lens laterally or by moving the object in front of the lens.

The record then contains a series of interlaced images which can be reconstituted by observation through a similar lenticular screen. In any one position of the screen relative to the image all the components belonging to one image are visible again as a continuous picture. On moving the viewpoint (e.g. the eye) or on shifting the screen relative to the multiple image, a different set of image components become visible, assembling a new picture.

Lenticular Colour Photography. One of the first systems of additive colour photography for motion pictures used a normal panchromatic emulsion embossed with a regular texture of cylindrical lenses. This lenticular structure was impressed on the film base, and the taking lens of the camera was fitted with a filter consisting of three bands of red, green and blue. On exposing the film through the base each cylindrical lens element focused a red, green and blue band (from the filters) on to the emulsion.

In each image of the filter, the red, green or blue area will only receive an exposure if that colour is reflected from that particular area of the subject. Thus a blue image point will produce a dense patch on development under the image of the blue filter band, but not under the images of the other filter bands which remain clear. On reversal processing the patch corresponding to the exposed area becomes transparent while the rest of the area covered by the tiny lens becomes opaque.

The film is projected through the same type of coloured filter. The white light passing through the clear patch is focused again by the lenticle through the corresponding colour band of the filter on to the screen.

LENTICULAR SCREEN. Seen in cross-section, the screen appears as a series of embossed cylindrical lens elements, which split up the image into strip elements.

All image points of the various colours of the scene are synthesized by the taking filter in this way and reproduced as more or less clear patches on the developed emulsion. On projection (with the emulsion facing away from the lens) these patches transmit white light. Its intensity is proportional to the brightness of the original subject at each point. The light is again directed by the lenticular screen through the corresponding colour bands of the projection filter and recombined to form an image in the colours of the original subject.

Stereo Photography. In one system of stereoscopic photography two lenses focus two images (corresponding to the left eye and right eye views) on to the same film through a lenticular screen. At the correct spacing of the lenses relative to the curvature of the lenticular elements the screen records the two images as a series of interlaced strips. After printing as a positive, the individual images are separated by viewing through a similar screen. The stereoscopic effect is limited to a fairly small viewing angle in front of the picture, but it is produced without the use of a special viewer or spectacles.

This type of stereo image is known as a parallax stereogram. In a more elaborate system a single taking lens moves during the exposure, while the film with the lenticular screen is moved in synchronism. If the movements are appropriately matched, the strip elements record a continuous change of viewpoint from the left-to the right-eye view. This yields a so-called parallax panoramagram. Reconstitution of the image takes place in the same way as with the stereogram, but the stereoscopic effect is continuous over a much wider viewing angle. A system of this kind has even been used for printing three-dimensional images by a mass printing process. The printed reproduction is covered with a layer of plastic into which the lenticular elements are impressed by a suitably machined heated roller.

Image Dissection. A lenticular plate can be used to split up and multiply an image for high-speed photography. With picture sequences at fast rates the necessary movement of the film to record one frame after another runs up against appreciable mechanical problems. If a lenticular system is used, the images can be broken up and recorded side by side in an interspersed fashion on the same sensitive surface; the required movement is then very much reduced, making greatly increased exposure speeds possible. A similar lenticular plate is used to "unscramble" the composite image frame by frame. This merely requires successive very slight movements of the lenticular plate relative to the image, to bring the lenticular elements into register with all the image points belonging to one picture.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MULTIPLE IMAGE FORMATION. The lens L projects its image via the lenticular screen S on the film F. The screen breaks up the image into line elements A with spaces in between. If the screen is moved (dotted) a new set of line elements B is formed in the spaces between the first set. With two crossed screens, dot elements are formed.

Multiple Image Storage. The same principle can also be used for micro-recording. Here a number of separate originals—for example pages of a book—are photographed in succession on to the same sheet of film. A lenticular screen is placed in front of the film. The image is thus split up and concentrated into dots which may occupy only a fraction of the space of the film surface.

For successive exposures the lenticular screen is slightly displaced, forming subsequent dot images in the spaces between the original one. This therefore yields the interlaced pattern of a multiple picture.

To unscramble the composite record it is then only necessary to project the developed negative through the lenticular screen. Progressive movement of the screen relative to the developed film projects successive images (the different originals copied in turn) on to the viewing screen or on successive sheets of copying paper.

Whenever lenticular dissection is used, this naturally limits the resolution of the image by the spacing of the lenticular elements. But the latter also expand optically the image points and thus produce a continuous and undistorted picture on projection. F.P., (L.A.M.)

LE PRINCE, LOUIS AIMÉ AUGUSTIN, 1842–90. French artist, chemist, inventor and pioneer of cinematography. Introduced to photography by Daguerre, friend of his father, saw Muybridge photographs in 1879 and started work on motion picture projection while living at Leeds. His U.S. patent application of 1886 (granted 1888) described a camera or projector with one or several lenses, use of flexible film, intermittent movement and obscuration. In 1888 took 12 to 20 pictures per second on film 2⅜ ins. wide (first sensitized paper film, later gelatin stripping film and finally celluloid-base film). His first cine film projections were witnessed in Leeds 1889 and Paris 1890. He disappeared without trace, on a journey, at Dijon, 16th September, 1890.

LEREBOURS, NOEL-MARIE-PAYMAL, French optician, publisher and photographer. Made some of the lenses for the original (official) daguerreotype apparatus put on the market 1839. Published in conjunction with Susse frères an edition of Daguerre's manuel, 1839. Sent artists to many countries to take daguerreotype views to illustrate *Excursions Daguerriennes* 1841–3. Introduced quarter-plate daguerreotype cameras with achromatic lenses for portraiture, 1840. Wrote several manuals on the daguerreotype process. Founder member of the Société Héliographique. Published, with others, under the title *Lithophotographie* (1853) large views with good half-tone using albumen on lithographic stone.

LE ROY, JEAN ACME, 1854–1932. American pioneer of cinematography. Worked on a device for projecting Edison Kinetoscope pictures on to a screen for a large audience and exhibited moving pictures in New York on 5th February, 1894. Exploited his invention as a showman, but never patented or commercialized it.

LERSKI. HELMAR, 1871–1956. Swiss actor who took up portrait photography in America in 1911. 1915–27, cameraman for German motion picture companies, then returned to portrait photography, first in Berlin, after 1931 in Israel. Specialized in close-ups of simple people, changing their expression and apparent personality by subtle lighting.

LE SECQ. HENRI (Jean-Louis-Henri Le Secq Destournelles), 1818–82. French painter and photographer. Chiefly known for his architectural photographs taken for the French Government, 1851. Also photographed for Blanquart-Evrard. Gave up photography in the late 1850s, and formed a museum of wrought-iron work at Rouen.

LETTERING. Some prints need a title—e.g., to indicate the name of the sitter in a portrait or of the place in a landscape. It is usual to letter the words by hand on the mount below the print, and many an otherwise good piece of work is ruined in the process. Photographers too often do not realize that hand lettering is an exacting form of skilled craftsmanship that takes years to master. Fortunately there are several ways in which the amateur can make a neat, workmanlike job of lettering a title without being an artist.

The only equipment necessary is a steel rule, H and HB pencils, and a sandpaper block. Pencils softer than HB should not be used or

the lettering will rub off when the print is handled or filed with other photographs. The sandpaper block is needed for keeping the point of the pencil sharp.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Simple Lettering. The simplest method is to fit the letters into rectangles roughly half as wide as they are high. All the letters of the alphabet can be fitted into such rectangles with the exception of M and W which need a little extra width. The style of the letters should be kept simple and the uprights should be at right angles to the base. Each line must be made with a single stroke of the pencil; it spoils the appearance of the letter to go over it more than once. If plain block letters look too stark, they can be improved by adding light serifs to produce a Roman type of lettering, but any further embellishment should be avoided. After all, the photograph is the important thing and the title should not compete with it for attention.

The title should be lettered on the mount, starting below the left-hand corner of the print and with about half an inch separating the bottom edge of the print and the top of the letters. First it is as well to letter the title between ruled lines on a spare sheet of paper and experiment with the letter spacing until the words look right and are easy to read with no ugly gaps or crowded letters. The back of the paper can then be rubbed over with a soft pencil and the lettering traced lightly through into place on the mount with a hard pencil. This takes care of the spacing and permits the title to be lettered on to the mount with confidence. Where the photographer wishes to include his own name, he should letter it in the same style as the title. An ordinary signature on the mount looks pretentious.

Other Methods. The ordinary draughtsman's celluloid stencils can be used for pencil lettering. But the mount should be pinned down on to a drawing board and the stencil positioned with a tee-square.

A title typed on a sheet of paper, cut out and pasted on to the mount can look neat and effective. It is generally better to use suitably tinted paper; white is apt to make the mount or the print look grubby.

LETTERING LAYOUT. Letters should fit into equal rectangles, except for specially wide ones (e.g., MW). Titles should be lettered simply and kept short.

Prints in albums may be titled by any of the above methods, although cut out typewritten words are usually more suitable as the pages of the album are usually black. White ink may also be used for tilting on black pages but mistakes are difficult to erase.

Photographic Christmas cards may be lettered by hand, but if a number are being turned out it is easier to draw out the lettering, photograph it, and print it in position along with the negative. There is no reason why old Christmas card titles should not be cut up to form the required words. The ready-made lettering on thin adhesive paper used by commercial artists may also be used for making up the title or greeting message to be photographed. P.C.P.

See also: *Caption; Greeting cards; Inks for photographs; Slide diagrams; Titles.*

LETTERPRESS. Method of mechanical printing from a raised surface which carries the ink. Derived from the fact that in the oldest and still most widespread printing process for text matter the letters stand up above the general surface. Half-tone blocks with a dot structure of raised dots are equally referred to as letterpress blocks.

See also: *Photomechanical reproduction.*

LEVELS AND PLUMBS. Devices to aid accurate horizontal and vertical alignment of cameras and other equipment. Levels are necessary in all kinds of survey photography, architectural work, stereoscopic photography, panoramas, etc. Plumbs are used in copying set-ups, architectural and surveying photography, etc.

A level (spirit level) consists essentially of a sealed glass tube filled with spirit, leaving a small air bubble. As long as the tube is truly horizontal, the bubble will lie exactly between reference marks in the middle. If the tube is inclined along its length, the bubble will move towards the upper end. This arrangement is very sensitive to the slightest inclination.

The level may be a separate accessory mounted in a suitable metal or wooden block with its under-surface absolutely parallel to the tube, or it may be built into the camera or other equipment. Built-in spirit levels are more commonly found on older-type stand cameras, and sometimes on modern tripods.

Some types of spirit level consist of a horizontal round cell instead of a tube. On truly level positioning the bubble should be in the middle of the flat top of the cell. This level shows departures from horizontal in any direction, not only along one axis as in the case of the tube level.

A plumb is a small weight attached to the end of a thin cord. When the weight hangs

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

freely from a fixed point, the cord provides a truly vertical reference—e.g., for setting up the camera accurately over a particular point on the ground.

A vertical spirit level, i.e., one set in one limb of an accurate T-square or similar instrument, will also serve for vertical alignment.

In some cameras a levelling indicator is visible in the viewfinder in the form of two pointers. When these are in line, the camera is level. L.A.M.

LEVY-DORN, MAX, 18??–1929. German roentgenologist. Made the first stereo-radiographs (1897) and the first cine-radiographs, also the first complete X-ray installation in a hospital in Berlin (1906). Stressed, as early as 1903, the need for protection from X-rays.

LIESEGANG, FRANZ PAUL, 1873–1946. German manufacturer of projection apparatus, son of Paul Johann Liesegang. Wrote much on the history of projection and on the forerunners of cinematography.

LIESEGANG, FRIEDRICH WILHELM EDUARD. 1803–69. German photographer. Founded the firm of Liesegang (Elberfeld, 1854, later Düsseldorf) which was carried on by his son and grandsons, eventually to merge, as the oldest component, into the Agfa concern. Manufactured at first projection apparatus; from 1857 on, also calotype materials and photographic papers.

LIESEGANG, PAUL EDUARD JOHANN, 1838–96. German photographic manufacturer, son of Friedrich Liesegang. Suggested green safelights for the darkroom in 1861. Introduced the Lilliput camera (3 × 3 cm.) in 1882. Founded several periodicals: *Photographisches Archiv* in 1860, *Photograph scher Almanach* in 1861, and *Laterna Magica* in 1877.

LIESEGANG, RAPHAEL EDUARD JULIUS, 1869–1947. German colloid chemist, son of Paul Johann Liesegang. Published experimental work on electrolytic development on photochromy, and on the bleach-out process. Described the principle of lenticular screen colour photography processes (1896). Author of many books and articles.

LIGHT. Light is merely one of the many forms of electro-magnetic radiation encountered in nature. Such radiations occur as radio, radar, radiant heat and infra-red therapeutic rays, visible light, ultra-violet rays, X-rays, and the gamma rays caused by the breakdown of certain atoms.

Electro-magnetic radiation will travel across empty space and needs no material conductor. All forms of it have the same velocity in vacuum—3×10^8 metres, or 186,000 miles, per second. The velocity in air is practically the same.

Corpuscular and Wave Theories. The first attempt to explain the nature of light was Newton's corpuscular theory. He postulated that light consisted of small corpuscles shot out from the light source rather like bullets from a machine gun. This explained reasonably well many of the optical phenomena known at the time. At about the same time Huygens suggested that light was a wave motion. The discovery, during the eighteenth century, of diffraction and inteference effects, and later the assumption that light was one of a number of electro-magnetic radiations, eventually gave preference to the wave theory as the more likely explanation of the nature of light.

The present view is that both aspects of light appear to have a degree of simultaneous existence. In other words, light can behave either as waves or as particles. The former are needed to explain diffraction, interference and the colour of different kinds of light; the latter are associated with energy aspects, including the interaction of light with matter to initiate chemical reactions. The formation of a photographic image in an emulsion is the most obvious example.

Wave Characteristics. When regarded as consisting of waves, electro magnetic radiation is associated with a definite frequency governed by the following relationship:

$$\text{Velocity} = \text{frequency} \times \text{wavelength}.$$

The frequency of a certain hue of blue-green light is, for example, 6×10^{14} cycles per second, and its wavelength is therefore $0{\cdot}5 \times 10^{-6}$ metres.

Physical interaction between light and material bodies leads to the phenomena of reflection, refraction and dispersion. Straightforward reflection, with the light ray thrown back from a surface virtually unchanged, is a characteristic of the action of mirrors. When light passes from one transparent medium to another—e.g., air to glass—its velocity and therefore its wavelength are changed. This is refraction, the phenomena to which the action of a lens is due.

The wavelength of light is so short that it must be measured in special units. The commonest is the Angstrom unit, which has as its symbol the capital A. There are ten million Angstrom units to the millimetre. It is sometimes more convenient to use larger units like the micron which is the thousandth part of a millimetre, or the millimicron ($m\mu$), which is the millionth part of a millimetre—i.e., one micron = 1000 millimicrons = 10,000 A.

The nanometer (nm.) is a more modern term for the millimicron.

So $0{\cdot}5 \times 10^{-6}$ metres, the wavelength of blue-green light, would be written as 500mμ or nm, or 5000A.

X-rays have such a short wavelength that

they are measured in x-units of which there are ten thousand million in a millimetre.

Photography is concerned with wavelengths ranging from a few mμ (X-ray range) to 1500 mμ.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Light as Energy. Like matter, light can be subdivided quantitatively until we arrive at the smallest basic unit. This is the photon and corresponds—at least in conception—to Newton's corpuscles. A photon is an elementary energy packet with one so-called quantum of energy. The size of this quantum depends on the wavelength of the light, and is defined as:

$$E = h\nu$$

where his Plank's constant and ν the frequency.

The effect of light in terms of exposure of a photographic emulsion is associated with light quanta. It is the energy of the light which initiates the reactions leading to the conversion of silver halide into metallic silver forming the image.

LIGHT GUIDE. Optical unit which can carry light rays along paths other than straight lines. Usually the term refers to glass rods or bundles of glass fibres which can be bent into any shape, but which ensure that a light ray entering the rod at one end will always emerge at the other. The light guide carries the light along its tortuous path by a series of successive internal reflections. As long as the guide is not bent to too small a radius virtually no light will be able to escape.

LIGHTING EQUIPMENT

In the early days of photography the sun was the only source of photographic lighting; with the development of electric lighting, photographers were quick to appreciate the advantages of a source that they could control. To-day as much, if not more, photography is carried out by electric light as by daylight, and the equipment available ranges from small portable units to permanent installations capable of creating any type of lighting effect and powerful enough to permit exposures of short fractions of a second.

The most popular sources of electric lighting are tungsten filament lamps of the normal and overrun (Photoflood) types. These are cheap, convenient and very suitable for most amateur and professional needs. Arc lamps of various types, vapour discharge and fluorescent lamps and flash, both bulb and electronic, have their special fields of operation.

Controls. Before a light source can be usefully employed for photography, there must be some means of controlling it.

The power of the light is controlled in the simplest fashion by the switch which turns it full on or off. It may be further controlled by inserting a dimming resistance in the circuit, or by series-parallel switching arrangements; by this means the power of the light is continuously variable between full power and off (dimming resistance), or adjustable to give full power, reduced power of a fixed value, and off (series-parallel switching).

The concentration of the light is controlled by shaped reflectors behind the light source, or lenses (spotlights) in front. In the case of reflectors, the light is spread and, depending on the surface of the reflector, somewhat diffused; this is useful for providing general illumination of fairly large areas. With a spotlight, the light can be concentrated on a smaller area and used to get crisper results with harder shadows. When maximum diffusion is required, a diffuser is fitted in front of either reflector or spotlight.

The colour of the light may be controlled by either the choice of the source, or the use of colour filters over the light. Such measures are only required in colour photography where colour temperature is of great importance.

The position of the light source is, in practice, the most fundamental of all controls. To enable convenient alteration of the light position, various supports, brackets, and stands are made so that the direction and angle of the light is adjustable with ease.

Amateur Outfit. Few amateurs have the space to spare for ambitious lighting equipment. In most cases the gear must be packed away after the photographic session, therefore it needs to be of the type that dismantles easily or telescopes into a small space.

While it is true that good pictures can be made with only one lamp, its range of effects is limited and exposures are apt to be unduly long. A good working compromise between such austerity and the elaborate set-up of the professional is provided by the following:

(1) Modelling light: one Photoflood or 500 watt tungsten lamp in reflector on an adjustable telescopic tripod stand. The adjustment should allow the lamp to be placed anywhere from four to eight feet from the floor. This lamp provides the main source of light; where it is not enough to cover the subject it can be supplemented by the fill-in light.

(2) Fill-in light: one Photoflood or 500 watt tungsten lamp in a shallow reflector on a small hook-or-stand support or on a clamp fitting. This light is normally required for illuminating the shadows, but it may be replaced by a flat white reflector so that it can be added to boost the modelling light—e.g., to cover a broader area.

(3) Background light: one 150 watt tungsten lamp in a deep reflector or fitted into a reading

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

lamp holder with a suitable cone of white paper to concentrate the light on the background. This light is used for controlling the general or local tone of the background, particularly in portraiture. It may also be used for back lighting to create a bright rim of light around the subject.

(4) Spotlight: although a spotlight is much more expensive than any of the other forms of lighting, it opens up a wide choice of special effects both in portraiture and still life, and it can be packed into a small space. For these reasons the serious amateur would complete his equipment with a 250 watt focusing spotlight with fittings for barndoor, snoot, lamp-filter and diffuser.

TYPICAL LIGHTING INSTALLATIONS

Equipment	*Watts*
Commercial Studio	
(Equipped for six cameras on still-life subjects)	
18 250 watt lamps in deep reflectors	4,500
12 500 watt spotlights	6,000
1 1,000 watt flood	1,000
1 7-amp enclosed arc (on 200 v.)...	1,400
Total	12,900
Large Portrait Studio	
4 Mercury vapour tubes, 200 watt	800
5 1,000 watt lamps in white-painted trough ...	5,000
2 1,000 watt floods	2,000
2 1,000 watt spotlights	2,000
2 500 watt spotlights	1,000
2 250 watt floor lights	500
1 1,000 watt spotlight with mirror reflector only	1,000
Total	12,300
Small Portrait Studio	
1 400 watt Mercury vapour tube; 2 500 watt Nitraphot in movable trough from ceiling, diffused	1,400
1 120 watt Mercury vapour tube; 1 500 watt Nitraphot in small white trough, diffused. Floor stand with counter-weighted arm ...	620
1 1,000 watt Daylight lamp in convertible studio light. Floor stand with large matt aluminium bowl. Direct or indirect light	1,000
1 500 watt Nitraphot with shallow blue-tinted bowl. Direct or indirect. Floor stand	500
1 1,000 watt Spotlight	1,000
1 500 watt Spotlight	500
Total	5,020
Studio of Daily Pictorial Newspaper	
1 2,000 watt spotlight	2,000
2 1,000 watt spotlight	2,000
1 20 amp. arc spotlight (on 230 v.)	4,600
3 1,000 watt floods, in 18 in. painted reflectors ...	3 000
Total	11,600
Back Projection Equipment	
1 50 amp. lantern with water cell (on 230 v.) ...	11,500
6 250 watt overhead spotlights	1,500
2 250 watt floor spotlights	500
Total	13,500
Commercial Sub-standard Cine Studio	
(This lighting equipment permits shooting on a 30 feet wide set at *f* 2 or *f* 2·5)	
50 275 watt Photofloods, overhead	13,750
8 500 watt ceiling floods	4,000
2 500 watt spotlights	1,000
2 1,000 watt spotlights	2,000
4 275 watt Photofloods in metal reflectors ...	1,100
Total	21,850

The total power consumption of all this equipment would not overload the normal room power supply.

A desirable extra is a switch—preferably the foot-operated type—connected to the two Photoflood lamps so that they can be switched in series for focusing and arranging the subject, or in parallel to give their maximum brilliance for the exposure.

There are several types of collapsible reflector on the market for amateurs who have no room to store rigid reflectors. These reflectors are never as good as the normal type, but they are satisfactory so long as they have a matt and not polished reflecting surface.

Commercial Studio. The lighting equipment of the commercial studio is dictated by the type of work undertaken. A studio specializing in one particular branch—e.g., portraiture or catalogue illustration—may be relatively lavish with equipment suited to that type of work but poorly equipped to handle general subjects. It may suit one studio better to have a number of mobile units and little in the way of fixed lighting, whereas another may need to have a number of fixed lights controlled by separate switches on a central panel.

The basic set-up in most studios consists broadly of the following:

(1) General lighting: banks of tungsten, mercury-vapour or fluorescent lamps in trough-type reflectors. These are suspended or built in above the camera position to direct a flood of general light forward on to the subject. They may be adjustable for height and position, and they are generally arranged in a number of separately switched units. The total power consumed by the general lighting of an average studio is often more than 10,000 watts.

(2) Effect lights: any number of tungsten lamps from 250 to 1,000 watts, mounted on adjustable mobile stands. These lights are brought up as required to give general or local modelling, fill-in, background and back lighting. The shape and size of the reflectors vary according to the purpose of the lamp—e.g., shallow and broad for supplementary general lighting, or deep and narrow for illuminating smaller areas.

(3) Spots: any number of fixed and focusing spotlights mounted on adjustable mobile stands with provision for inserting masks, filters, barndoors, hoods, snoots, etc.

The spotlights, because of their power and flexibility (in position, and in breadth and shape of beam) tend to be used for all the principal work of modelling. Light sources may be either projector-type tungsten lamps, or carbon, mercury or high intensity arcs, ranging from 500 to 2,000 watts or more.

In studios which specialize in popular and "while-you-wait" portraiture the principal lights are often fixed arrangements disposed around the walls and over and in front of the sitter's chair. Any of a number of types of subject

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

lighting can be produced by pressing the appropriate switches. This is quicker than moving lights about, and the exposures can be standardized. With very little training an operator can take charge of such a studio and turn out a portrait to a set pattern in a few minutes. The photographs produced by such lighting arrangements are apt to be stereotyped.

Control Boxes. Where a number of independent lamp units in a photographic studio are used at the same time, they may conveniently be controlled from a lighting control box. In its simplest form this is a sheet metal box on rubber feet or castors, with two or more switched socket outlets connected in parallel to a tough rubber-sheathed cable and plug which connects the box to the mains socket outlet. This allows two or more lighting units (depending on the number of outlets provided) to be plugged in and switched on and off individually. It also allows the lighting to be controlled from anywhere in the studio irrespective of the position of the permanent socket outlet.

In addition to the switches on each of the separate sockets, the control box may provide other facilities. Certain outlets (e.g. for photoflood lamps) may be associated with a series/parallel switch allowing pairs of lamps to be run in series while the subject is being arranged and then switched to parallel working for maximum brilliance during exposure.

One or more socket outlets on the box may be connected to a variable resistance controlled by a hand wheel on the outside of the box to allow a bank of floodlights or a spotlight to be dimmed at will.

The control box usually incorporates a pilot lamp which lights up when the box is connected to the mains to show that outlets are live.

Another type of box, popular for amateur studio lighting, allows an even number of photofloods to be connected as two groups in series or parallel by pressing a foot switch mounted on the box.

Voltage Control. Variations in the voltage of the electricity supply used for studio lighting affect both the total light output and the colour temperature of the lamps. This is particularly important in colour photography, where a supply of constant voltage is essential.

One means of providing this is an autotransformer connected to the alternating current supply. Tappings on the secondary winding are connected to a continuously variable control so that the transformer ratio can be altered to give a constant output voltage for every value of supply volts between the upper and lower permissible limits of supply voltage variation. A meter across the secondary of the transformer allows the voltage to be kept at a constant figure by turning the control up or down as required. This type of control can be used for either keeping the supply at a constant voltage or for providing a range of output voltages from a given supply.

Where the only purpose is to maintain a constant voltage the job can be done automatically by a constant voltage transformer (CVT). This makes use of a control circuit consisting of a separate coil wound on a saturated iron core and connected in opposition to the main winding. This is done in such a way that an increase in the supply voltage is cancelled out by an opposing voltage of the same value in the control winding while a drop in the supply volts is compensated for by a greater drop in the opposing volts. Once again the net result is that the useful voltage of the transformer remains unchanged.

As an alternative, the voltage can be controlled by a variable resistor (rheostat) wired in series with the lamp circuit. The resistance required at any one time depends on the resistance of the rest of the circuit, hence rheostats must be selected individually for the requirements of the equipment being controlled.

A rheostat has the advantage that it can be used with direct (D.C.) as well as alternating current (A.C.), and rheostats are sometimes employed as dimmers where a continuous variability of light output is needed. However, when the voltage is reduced with a rheostat, an appreciable amount of current is wasted and converted into heat. For that reason transformers are preferred to resistors in virtually all cases where an A.C. supply is available.

Colour Temperature Control. To provide direct control of the colour temperature of tungsten filament studio lighting, an auto transformer may be used with a series of tappings covering a range of voltages from some 50 per cent below to 50 per cent above the normal supply voltage. A rotary or sliding control allows any voltage to be applied to the lamps according to the colour temperature required, a higher voltage raising both the colour temperature and the level of the lighting and vice versa.

One form of control box designed specially for still and cine photographic studios combines all the separate pieces of equipment required for colour temperature control: autotransformer, voltage selector and indicators for showing colour temperature and lighting level. This type of unit helps to extend the useful life of photographic lamps since it allows them to be under-run while the subject is being arranged and then brought up to the required colour temperature for the actual exposure. The saving can be considerable when it is remembered that the life of a 1000 watt studio flood varies from 2,000 hours under normal conditions to 12 when over-run to give a colour temperature of 3,400°K. F.P.

LIGHTING THE SUBJECT

The photographer who works out of doors in daylight must take the subject lighting as he finds it. Up to a point he can select the kind of lighting he wants from variations in direction, intensity and character of the sun's light in the course of the day, or the season, or the weather. He can modify the lighting of near subjects by the use of a reflector or supplementary flash. But he has no control over the principal lighting and in fact he has little wish to exercise control since the natural lighting is part of the character of the subject.

Things are different when he comes to take a picture indoors. Here he has complete control of the lighting of the subject. This time, he not only has to select, arrange and compose his picture material—he has to light it. And whereas the lighting of a picture that was obviously taken out of doors is accepted by most people without challenge, the lighting of an indoor photograph is as fair a ground for the critic as the composition. To a very great extent, the lighting is the picture; and the success of the result depends upon understanding how much to use and where to put it.

The tools are simple and few; there is the spotlight, which gives a hard and relatively narrow beam of light; the floodlight, which gives a broad, soft, general illumination; and various types of light reflector—e.g., white or aluminium-surfaced flat boards—which reflect more or less diffused light on to the subject.

The effect of any single light on the appearance of the subject can be controlled in a number of ways.

(1) The angle of the rays falling on the subject may be varied—i.e., the lamp may shine either horizontally, or from vertically above or below, or from any intermediate angle.

(2) The position of the light may be varied, making the lamp shine from in front, from behind, or from any intermediate point.

(3) The distance from the subject may be changed from near to far.

(4) The power of the lamp may be varied according to the consumption or type of the light source chosen.

(5) The softness and spread of the rays may be changed by letting them shine through a translucent diffusing screen—e.g., of stretched white muslin.

(6) The colour temperature may be controlled by the use of tinted filters in front of the lamp.

All these various forms of control can be exercised with a single light source. But any number of single sources may be used at the same time, and each one may be varied in any of the six ways independently of the others i.e., with two lamps, there are six ways in which the effect of either lamp may be altered, associated with six states of the other. So that with only two lamps in use, there are thirty-six ranges of lighting effect, and since each range of effects offers anything up to another dozen recognizably different effects, the photographer is faced with an embarrassing number of alternatives in arranging the lighting. And as the number of lights increases, things get more complicated.

So a haphazard experimental approach is out of the question. Correct subject lighting follows as a logical result only when the photographer can visualize the characteristic effects of the basic lighting conditions; he has already in his mind a picture of how he wants the subject to look, and he places his lights to give the effect corresponding to his mental picture.

It does not follow, however, that by employing all of these lighting effects a better picture will be achieved.

BASIC LIGHTING CONDITIONS

It is first of all necessary to recognize the basic lighting conditions. Five lighting conditions give characteristic effects which can be easily recognized. These are when the light, in relation to the subject (not the camera), comes from front, side, behind, top, below. (In practice these basic conditions are rarely used; it is more usual to combine the separate characters of two or more by adopting a compromise.)

Frontal Lighting, When the light shines on to the front of the subject it casts no definite shadows that are visible from the camera position. So the subject appears completely without relief; it is recognizable only by its shape against the background, and by its own differences of colour and tone. Where the surface of the subject curves away from the camera, however —e.g., along the sides of the cheeks and neck in a full-face portrait—less of the light is reflected back to the camera, so the tone is proportionately darker.

Frontal lighting is called "flat" or "shadowless" lighting; it can give a high key picture of

FRONT LIGHTING. The lamp should be slightly above the camera level to provide some modelling. At its best the effect is invariably rather flat with very little shadow.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

subjects which have no strong colour or tone contrasts of their own; it is the lighting generally recommended for straightforward colour photography because the illumination of all the colours is substantially equal and therefore the colours are more likely to come within the exposure range of the colour film.

Frontal lighting is often encountered in everyday life when the sun shines from behind the observer, so it is accepted as normal and calls up no special associations.

Side Lighting. When the light shines from one side on to the subject, it illuminates that side brightly and leaves the other in complete darkness. The result is to make the subject appear to stand out in strong relief because any feature that projects—e.g., the nose in a full-face portrait—reproduces as a highlight with an associated strong black area. The black area consists of the unlighted part of the projection and the shadow cast by the projection on the adjacent surface. A depression in the surface of the subject shows up as a highlight on the edge farthest from the light source and a shadow area on the same side as the light source.

Side lighting is common in normal, everyday experience and is easily accepted as natural.

Top Lighting. When the light shines from directly over the subject it casts all shadows vertically downwards over the subject. Generally, it highlights the features in the same way as side lighting—i.e., it emphasizes projecting features and depressions by reproducing them as areas of associated strong light and shade. Top lighting is not a normal effect away from the tropics, so it looks unnatural even when produced by artificial light.

Lighting from Below. When the light shines from below, the shadows are cast upwards. Projecting features are brightly lighted on the lower side and the upper surfaces are in shadow. The shadow on the side of projecting features joins up to the cast shadow to make a single black area.

This effect never occurs in nature so it looks completely false. The most familiar example of such lighting is the light of theatre stage footlights so, possibly by association, lighting from below has come to suggest drama and artificiality.

TOP LIGHTING. Throws features facing the camera into relief. All shadows are cast downwards, and the effect is not a natural one. It can, however, be used as effect lighting.

Lighting from Behind. When the light shines from behind the subject, all shadows are cast towards the observer. If the light is directly behind, the only indication of its presence may be a brilliant rim of light produced when the rays are reflected from surface roughnesses, fibres or hairs, the general effect looking something like an eclipse of the sun. This rim of light becomes wider as the lamp moves around towards the side, top, or bottom of the subject.

Rim lighting and backlighting are common in subjects seen against the rising or setting sun, so they are not unnatural in their effect. At the same time they leave the front of the subject completely in shadow, so they are rarely used as a sole source of photographic lighting. When they are used, it is as effect lights and not as principal illumination.

The Basic Lights. There is no limit to the number of lights that can be employed or the number of ways in which they can be arranged to provide a scheme of subject lighting. But there are only four functions that any particular light source can fulfil (although one light source may answer more than one of these purposes at a time)—i.e., it may be the principal (or modelling) light, a fill-in light, an effect light or it may light up the background.

SIDE LIGHTING. Throws features facing the camera into bold relief. Brilliantly lights one side of the subject, leaving the other in deep shadow, unless filled in by reflectors.

LIGHTING FROM BELOW. Shadows are cast upwards, producing theatrical and dramatic effects. The light should not be too low, otherwise the result looks weird.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

REAR LIGHTING. Leaves the subject as a detailless silhouette, usually with a brilliant rim of light outlining the subject shape. Mostly used as effect lighting only.

Principal Light. In every scheme there is one light that dominates all others; it creates the most noticeable highlights and it casts the most important shadows. This is the light that "holds the picture together" and its power and position must be adjusted so that its purpose is obvious. If any other light in the system is strong enough to compete with the principal light it will divide the interest, possibly produce conflicting shadows, and the picture will generally be confusing and incoherent.

Fill-in Light. The job of the fill-in light is to illuminate the shadows cast by the principal light.

The photographic emulsion is not able to register satisfactorily such a great contrast range as the human eye, so while the eye may still be able to discern detail in the shadows cast by the principal light, the camera might reproduce them as featureless black patches. So more light must be directed into the shadows to bring the over-all contrast of the subject within the range of the sensitized material.

A reasonable balance between highlight and shadow illumination is achieved when the shadow brightness is approximately one-third of the highlight. This condition may be created by adjusting the distance between the fill-in light and the subject, or by altering the power of the light sources.

The position of the fill-in light must be chosen so that it illuminates the shadows cast by the principal light but casts no new shadows that would be visible from the camera. The fill-in light is almost always provided by a floodlight giving a soft and evenly distributed illumination.

Reflectors of various types can be used in place of fill-in lights, both out of doors in sunshine and in the studio. While not being quite as versatile as a fill-in light, these are often more portable and convenient.

Effect Light. An effect light is one that is directed on to the subject with the aim of producing a distinctive highlight—e.g., a bright rim, a highlight on hair or cheek in a portrait—or of adding extra sparkle and brilliance. One of the most common effect lights is a light placed behind the subject and shining towards the camera to give a halo of light around the subject. Any number of such effect lights may be introduced, and they may be provided by spotlights, floods, or even reflectors. Mirrors are particularly useful for this kind of illumination.

Background Light. The background of subjects photographed in daylight is a matter for selection; it may be empty or furnished with objects, it may be brightly lighted or in shadow according to how the photographer takes the picture, but in every case, it is already there. In artificial light photographs, the photographer creates the background; nothing will appear in the finished picture unless he has put it there and then either intentionally or accidentally directed light on to it.

The photographer may choose a flat, plain, neutral tinted background for his subject, or it may be curved, textured or printed with a pattern; but the amount that appears in the finished picture, and the brilliance of its tone in relation to the subject, is a matter of lighting. It is possible to concentrate on the subject lighting and trust to luck that whatever incidental light falls on the background will produce a passable effect. (This is the characteristic approach of the beginner who forgets about the background until it turns up in the finished print to remind him unpleasantly of his oversight in arranging the subject.)

In all serious work, however, the background is separately lighted by a specially arranged background light. This may be supplied from a spot or a flood, depending on whether the light is to be spread evenly or concentrated.

Where a spotlight is used, the shape of the patch of light projected on to the background may be altered by manipulating the focusing adjustment, by altering the angle at which the beam strikes the surface and by employing masks (e.g., "barndoors") in front of the spotlight so as to cast a shadow.

Where a floodlight is used, the area illuminated can be controlled by turning the lamp and reflector and by supporting a shaped piece of card in front of the light to cast a shadow over part of the surface.

The broad object of background lighting is to create a tone contrast between the background and the part of the subject that appears against it. In the simplest case, where the subject is lighted from one side, the background is lighted so that the shadow side of the subject is seen against a light tone and the lighted side against a dark tone. It may be brightly lighted all over so that the entire edge of the subject stands out in a darker tone than the background. Or it may be given a low level of illumination so that all the edges of the subject appear brighter by contrast. The range of effects is infinite and completely under control, but it can never be left to chance; the background lighting is as much a part of the picture as the subject lighting itself.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Reflectors. Where there is already one source of illumination, the effect of a second source can be created within limits by using suitably disposed reflecting surfaces. These generally consist of flat boards painted with white enamel or aluminium paint, stretched sheets of white fabric or even sheets of white drawing paper. A reflector of this type can be arranged so that it intercepts rays from a light source and reflects them in another direction. A reflector with a perfectly polished surface reflects the light in straight lines, in the same way as a mirror, whereas the more usual matt white surface scatters the rays and behaves like a weak and very diffused floodlight.

Most of the basic lighting conditions can be reproduced approximately by suitably placed reflectors so long as the position and angle of the true light source lends itself to the arrangement. For instance, when the light source is in front of the subject, a reflector can be arranged to direct part of its rays on to the sides, top, bottom, or back of the subject—but not on to the front.

A reflector may also be used to reflect all the light from the source so that no direct rays from the source fall on the subject. This may be done to create a softly diffused source of light where the direct rays would give too hard an effect—as when a flash is "bounced" off a light-coloured wall or ceiling.

A reflector may thus be regarded as a weak and diffused supplementary light source. Its feeble character can generally be offset by placing it close to the subject, and even its diffusion can be overcome by using a mirror instead of a white surface.

SHADOWS

Shadows are inseparable from almost every lighting arrangement. The only position from which a lamp casts no shadows that will come out in the photograph is from the position of the camera itself. From all other positions, every light source casts a shadow that may or may not reproduce in the print. Generally speaking any light source in the lighting arrangement is bound to cast shadows that reproduce in the print—otherwise it would not be doing a useful job. And it is a safe rule that any shadow that can be detected in the actual set-up will appear darker in the final print.

The quality, size and shape of the shadow vary according to the effective area of the light source, the size of the object casting the shadow, and the relative distances of the source and the object from the surface on which the shadow is cast.

Quality of the Shadow. The light source affects the quality—i.e., tone and sharpness—of the shadow according to the effective area of the source.

A point source of light without a reflector will cast on to a surface perfectly sharp

SHADOW FORMATION. Top: *A parallel beam from a spotlamp casts a sharp shadow of the subject in approximately the same size.* Centre: *A point source casts a sharp shadow larger than the subject.* Bottom: *A larger source casts a diffused shadow of a dark core and a blurred lighter rim (a penumbra).*

shadows of any opaque object; this applies no matter what distance there is between light source, object and surface. But the closer the light is brought to the object, the bigger the scale of the shadow, and the closer the surface is brought to the object, the smaller the shadow. In every case, the shadow will be equally dense all over.

A source of parallel light rays—e.g., a spotlight—casts a sharp shadow that is always exactly the same size as the object, no matter how far the object and the surface may be from the source. Here again, the shadow density is the same from edge to edge.

What happens with a source of a definite size—e.g., a pearl Photoflood bulb—can be understood by visualizing the shadows cast by two light sources side by side. Each source will cast a separate shadow of the object on the background and if the lamps are far enough apart, rays from the lamp on the one side will fall on the shadow cast by the lamp on the other. So each shadow will be lighter in tone than if the second lamp had not been there.

If the lamps are brought closer together, the cast shadows will approach each other and finally meet and overlap. Where the two overlap there will be an area of deep shadow receiving no illumination at all, flanked by areas of lighter tone where the shadow cast by one lamp is illuminated by the other.

The same thing happens with a broad light

CC-0. Anemnia Digital Preservation Foundation, Chandigarh

source such as a floodlight or a photoflood reflector in a matt reflector. Such sources can be regarded as being made up of a number of point sources placed side by side. So the cast shadow will consist of a dark central area bounded by lighter areas where the shadow cast by one edge of the source is illuminated by light rays from the opposite edge.

The dark centre of such cast shadows is known as the umbra, and the lighter fringe as the penumbra. Generally, the broader the source and the closer it is to the object, the wider the penumbra. And the smaller the source and the farther it is away from the object, the narrower the penumbra

The effect of the penumbra is to soften the edge of the shadow. In practice, the sharpness of the edge of the shadow calls for careful control in relation to its purpose; generally, a sharply defined shadow attracts more attention than one that is softly diffused.

Size of the Shadow. This is governed by the relative distances separating the light source, the object and the surface on which the shadow is cast (except in the case of the spotlight type of illumination). As the light source approaches the object, the shadow grows bigger and as the object gets closer to the surface the shadow grows smaller. By adjusting the relative position of subject, light source and background in this way, the photographer can introduce background shadows of the subject—or any suitably shaped object—into the picture. The shadows can be either large and dominating, or small and subordinate according to the arrangement employed.

Shape of the Shadow. If the background is flat and at right angles to the beam of light, the cast shadow is a scale reproduction of the projection of the object. Since this type of shadow is simply a straightforward silhouette of the subject, it is uninteresting and rarely worth including in the picture. But when the shadow falls at an oblique angle, it becomes distorted—generally in some interesting way—and can make a valuable contribution to the composition. The distortion can be varied still further by curving the background in any direction. Here again the range of effects obtainable extends the power of the photographer to express his ideas in terms of light and shade.

Shadow and Subject. There are generally two surfaces on which the lighting casts a shadow of the subject: the background and the supporting surface—e.g., the table or bench, or the floor on which the subject stands. In some circumstances both these shadows will appear in the picture, in others, only one of them, and both can if necessary be removed by various means.

Shadows on the Background. When the subject is lighted from the front, its shadow will fall directly behind it on the background and the camera will not see it. When the light shines at an oblique angle from the side or above the

SHADOW POSITION. Top: *With front lighting the shadow is cast directly behind the subject, while top lighting or side lighting moves the shadow down or to one side respectively. This helps to separate subject and shadow.* Bottom: *With a given light position, a level camera position includes less of the shadow in the picture than a high camera angle.*

subject the shadow will fall too far away to be included in the picture area. In all such cases the photographer can ignore the shadow of the subject when he is arranging the background. If there is an unwanted area of shadow cast by oblique lighting, he can make it fall outside the picture area by simply moving the subject away from the background.

But in all intermediate lighting positions the shadow of the subject falls inside the picture area. It is part of the picture, and as such, it is subject to all the methods of control described above—i.e., it can be varied in density, sharpness, size and shape. In addition, the shape of the shadow can be altered by turning the subject in relation to the light and the background, and its tone can be made lighter by directing a light on to it from the front or side. If necessary, the whole shadow or only a part of it can be made to disappear by lighting it in this way with a flood or spotlight.

Shadows on the Support. Normally the shadow on the support—e.g., the floor—is not so much in evidence as the part that falls on the background. There are two reasons for this: because the camera sees less of the horizontal surface of the support than of the vertical surface of the background, and for the psychological reason that the shadow on the support is accepted as a natural part of the subject. Everything resting on a surface (as

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

most things do) casts a shadow on that surface and in fact this kind of shadow is more likely to be missed when it is not there than noticed when it is.

When the camera looks down on the subject, the shadow on the support becomes more noticeable and it can be made even more so by appropriate lighting—e.g., low-angle lighting will produce unusually long shadows.

But there are occasions when the shadow is just a distraction—e.g., in catalogue illustrations and the like. To attempt to "kill" the shadow with another light might simply add another shadow on the opposite side of the subject. The correct method, whenever practicable, is to rest the subject horizontally on a sheet of glass supported above a sheet of white paper. This white paper is in effect a background and may be illuminated either by a special light or by the subject lighting. If the subject lighting provides the "background" light then it must fall at such an angle that the cast shadow lies outside the picture area.

This method of supporting the subject also makes it possible to light it from below to get rid of shadow areas in which the detail would otherwise be lost—an important point in illustrations of products for catalogues, advertisements and instruction books.

STANDARD LIGHTING ARRANGEMENTS

Lighting to the photographer is what brush and paints are to the artist and one should be as free to express himself in his own way with his materials as the other. The last thing a photographer should seek to do is to copy slavishly any so-called standardized method of lighting. At the same time, while he ought not to be concerned with any such arrangement as a goal, he can save himself a lot of trouble and experiment by using it as a point of departure from which to develop.

Broadly speaking, the subject lighting may be arranged to reproduce either modelling or texture. In addition there are a number of special effects: silhouettes, shadowless lighting, high and low-key lighting, lighting for the photography of polished surfaces, and sometimes lighting for a given contrast range.

Lighting for Modelling. In normal straightforward photography of people, solid objects, and three-dimensional subjects in general, the aim of the lighting is to convey the depth and roundness of the subject. It does this by making one side of the subject light and the other dark, with a gradual transition from one to the other where the surface is curved. It creates planes of differing tone values in which the nearer parts of the subject contrast with those farther away. As the natural light out of doors shines downwards, the most natural effect is achieved by making the principal light shine downwards on the subject too.

So the basic position for the principal light

BUILDING UP A LIGHTING SET-UP. 1. The principal light is a floodlamp to one side of the camera, shining down on the subject. This provides the main modelling. 2. A diffused flood is added as a fill-in light from the front and on the same level as the subject. 3. A spotlamp is introduced to light up the background. 4. A second spotlamp acting as effect light (in this case a side-rim light) completes the basic set-up.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

to achieve natural modelling is above, in front of, and more or less to one side of the subject—e.g., with the angle of the beam at 45° to the front of the subject in both horizontal and vertical planes. In this position the light illuminates something like two-thirds of the visible part of rounded objects like a ball or the human head and leaves the rest in shadow. There is no sharp dividing line between the two areas and the smooth change over from highlight to deep shadow suggests the roundness of the surface. But the part of the subject that receives no light will be completely black and featureless. In practice, enough stray reflected light usually reaches even the deepest shadows to enable the eye to detect some detail there, but the illumination is much too weak for the sensitized material to record it. The result is that the shadows print out as solid blacks.

This is why a fill-in light is necessary. The purpose of the fill-in light is to light up the shadow side of the subject (but without casting any visible shadows of its own). Raising the level of the shadow illumination in this way reveals enough detail to make the dark tones interesting and narrows the over-all contrast range so that all the tones can register in proportionate densities in the photograph.

Normally the best position for the fill-in light is as close to the camera as possible. In this position it casts no shadows that are visible from the camera station and it illuminates all the shadows cast by the modelling light that are visible from that point. A reflector can be made to serve instead of an actual light source but its scope is more limited and for it to provide enough illumination it may have to be brought so close to the subject that it intrudes into the picture area.

Lighting the Background. At this point the subject will appear naturally lighted with highlights on the top and one side and more or less luminous shadow areas on the opposite side and below. It will look nicely rounded, but the shadow side will tend to be lost against the dark background and in a portrait the hair will tend to look lifeless.

The tone of the background must now be adjusted by adding background lighting. There are no rigid rules about this; the subject may call for a plain neutral tone provided by a broadly dispersed floodlight, or any of the light and shade effects obtainable with a spotlight or masked flood. This stage in the light is dictated by the photographer's mental picture of how he wants his subject to look. Generally the level of the background illumination should be below that of the subject, but there are occasions when a brightly illuminated background and a comparatively dark subject may be more appropriate.

Lighting the background will make the edge of the shadow side of the subject visible and for many subjects the lighting will now be satisfactory. But while the modelling of the subject will be satisfactory up to a point, the general appearance will suggest that it consists of only the front half stuck on to the background—i.e., an orange against a white background would look like half an orange with its flat surface against a white wall.

A final suggestion of roundness and depth can be given by the use of back lighting. The back light is placed so that its rays strike the side of the subject and create a rim of light which is visible from the camera position. (The lens must be screened from the rays of the back light by a deep hood and the light itself must be carefully controlled to prevent any rays from striking the lens.)

The bright rim of light, fading towards the front of the subject, creates an illusion of depth that was previously absent. It pulls the subject away from the background and makes it clear that it occupies a position in space between the observer and the plane of the background.

The lighting set-up now provides a sound system of basic lighting for modelling that will serve for most subjects. By varying the power and character of the lighting the general effect can be varied within wide limits without departing from the basic principles.

Profile Lighting. Where the interest of the subject lies in the outline, there are two methods of lighting that will emphasize it—profile lighting, which shows a bright outline of the subject against a dark background, and silhouette lighting which shows a dark or even black outline against a comparatively much lighter or white background.

Profile lighting is often employed in portraiture where this aspect of the sitter's face is the most characteristic. It is created by a back light so placed that its rays strike the edge of the subject at an angle of about 45° from behind and above. This illuminates a narrow band around one side of the subject and fades into darkness towards the front. The background may be lighted to throw up the shadow side of the subject while leaving the lighted profile to appear against a dark background. Or the whole shadow side of the subject may be left to merge into an unlighted background to emphasize the outline of light around the opposite side.

This lighting technique is effective for nude figures studies.

Although the bright outline is the interesting feature in this type of lighting, it is generally advisable to show something of the rest of the subject. This can conveniently be done by throwing back some of the profile lighting with a reflector facing away from the camera. The same result can be arrived at by using a very subdued fill-in light from the camera position.

Profile lighting is frequently used as an effect in conjunction with straightforward modelling lighting, particularly in glamour portraiture. In this case it may be used from one side or both.

Silhouette Lighting. In silhouette lighting the subject is shown as a more or less solid black shape against a light background. The aim here is to illuminate the background brightly, and the subject not at all.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

One effective way of doing this is to pose the subject against a thin and uncreased white sheet or tablecloth and make the exposure by firing a flash directed at the back of the sheet, opposite the subject.

The same effect can be produced by lighting a white background with a floodlight placed behind the subject. With this method there is more risk that stray light will be reflected on to the front of the subject.

Here again, the silhouette technique is often combined with other lighting so that while the main lighting emphasizes the significant profile, the secondary lights pick out other features necessary to the final effect.

LIGHTING DIFFERENT MATERIALS

Surface texture is one of the most important and revealing characteristics of many materials, and it expresses itself in the form of uniform unevenness of one sort or another. This unevenness is a manifestation on the surface of the material of its essential grain or structure. A polished surface has no texture in the accepted sense of the word, yet the fact that it can take and retain a polish suggests a dense, hard structure—e.g., glass, chromium plate, diamond. But the rough, splintered face of sawn timber speaks directly of its fibrous texture, just as the hairy nap on a piece of Harris tweed or the smooth sheen of a piece of silk conveys a clear impression of the physical nature of the material.

LIGHTING FOR TEXTURE. Top: *Very low oblique lighting emphasizes texture by casting pronounced shadows of surface detail and unevennesses.* Centre: *Oblique lighting shows up texture naturally by providing normal modelling.* Bottom: *Front lighting illuminates all the shadows evenly, and thus kills the texture effect, making the subject look completely flat.*

In many subjects texture is as important as shape and modelling. It is an essential feature in photographs of materials—e.g., fabrics, leather, wood—and it is also vital in portraiture, where the appearance of the skin—smooth and rounded or rough and wrinkled—says so much about the age and character of the subject. The texture of food, fruit and flowers seen close up can evoke many of the actual physical sensations of the real thing.

Broadly speaking, texture is revealed by side lighting and obliterated by frontal lighting. When the light strikes the surface at such an acute angle that it just skims the surface, the tiniest projection will be brilliantly lighted on one side and cast exaggerated shadows on the other. If the light comes from a point source, or from a parallel beam—e.g., from a focusing spotlight—the cast shadow will be sharp and incisive. The surface texture will be emphasized and sharpened by this treatment, whereas, if the light is diffused, the cast shadows will be blurred and the texture softened.

The type and angle of lighting used to bring out the surface texture will depend on the material being photographed. The hard, low-angle lighting that would be quite suitable for a piece of canvas would make velvet look bristly and stiff instead of silky and pliable.

A fill-in light is just as necessary here as in normal lighting. Without some illumination in the shadows, they would appear inky black in the print. This might be an advantage with subjects that call for the greatest possible emphasis of texture, but generally the photograph will be better for some shadow illumination provided by a fill-in light or reflector shining from the camera position. Again, the more powerful the fill-in light the less prominent the texture will be.

One of the problems of reproducing texture arises when it is to appear simply as an extra in a normal photograph. In such cases the modelling and the texture lighting would combine to give an unnatural or positively displeasing effect. Draped materials, for example, would call for careful modelling to show the soft roundness and depth of the folds. To introduce strong cross lighting for texture would defeat the object of the principal lighting.

In such cases the answer is to arrange the main lighting to give the best modelling over most of the subject and then to indicate the texture by a suitably placed rim light. Where the near margin of the rim lighting just begins to fade out, the rays glance off the surface of the subject at an extremely acute angle and emphasize the texture strongly. When this

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

technique is applied to a sufficiently strong point in the picture, the eye accepts the suggestion of texture as applying to all the subject.

Polish. Strictly speaking, polished surfaces show nothing of the texture of the material, but if the polish is an essential feature of the subject, it must be reproduced in the photograph. Polish is indicated by light reflections, but there is nothing gained by allowing extensive areas of the surface of the subject to be taken up with uninteresting patches of light toned reflections or distorted images of the light sources. A few odd catchlights are all that is necessary to show that the surface is polished. With many subjects considerable skill and a measure of compromise are required to reduce the surface reflections to a catchlight or two. The effect can be judged only by examining the image on the focusing screen or by viewing the subject from the same position as the camera lens. It may be necessary to move the principal lighting to get rid of major reflections and introduce a small, carefully controlled spot to provide the catchlight on the polished surface.

When a polished surface has a pattern—e.g., the grain of wood—reflections mask the pattern and are therefore undesirable. Moving the lights to get rid of the reflection may produce bad subject lighting, and any of the tricks of dulling the surface would obliterate the pattern or marking.

In these circumstances the answer may be to use a polarizing screen in front of the lens. This can be rotated until the unwanted reflections (which consist mainly of polarized rays) are absorbed; the surface markings will then be visible. A polarizing screen has no effect on light reflected from metal surfaces, however, since these rays are not polarized when reflected unless the light source itself is polarized.

Sheen. Many materials have a glossy surface combined with a rough or irregular texture—e.g., skin, silk, ornamental leather, feathers, and fur. In such materials the polished surfaces are neither large nor flat enough to produce directional reflection, but they combine to give a sheen or gloss to the material. This sheen is a characteristic that must be preserved in the photograph but it cannot be captured by texture lighting. Oblique lighting emphasizes the physical texture but falls at the wrong angle to reflect the glossiness. On the other hand, a broad soft flood of light from a high, frontal angle will give plenty of reflection but tend to flatten the physical texture of the surface. If it is necessary to reproduce both, the answer is to arrange the principal lighting to emphasize the sheen and a rim light to suggest the texture.

Translucence. Some materials, while they are by no means transparent, will allow light to disperse through them—e.g., flesh, hair, many of the plastics, flower petals and leaves. This translucence can only be revealed by rays travelling towards the camera. Such rays strike the subject and penetrate the surface, lighting it up with a luminous glow that radiates in the direction of the camera. When the lights fall on the front of the subject this glow is invisible and the material looks dead.

Materials. The standard techniques employed for rendering the texture of a number of common materials are described briefly below.

Damask and patterned materials: normal lighting to give modelling to the folds with a contrast filter for the pattern.

Flowers, foliage, fruit: soft, normal lighting with effect lighting from behind and above to show translucence and add rim light to pick out shape and texture. Opaque subjects are best lighted from the side with plenty of soft fill-in lighting.

Glassware: (1) for catalogue-style illustrations, normal lighting using a point source—e.g., a carbon arc spot—as the principal light to give sharply defined shadow. The shadow must not be exaggerated and a careful watch must be kept for excessive reflections and catchlights.

(2) Experimental treatment making use of exaggerated patterns of shadows and highlights created by refraction in the glass. The background or support on which the shadows are cast needs to be close to or touching the subject. Here again much can be done with point source illumination.

(3) Silhouette treatment created by photographing the subject against a lighted background. The effect is more delicate if the subject is supported horizontally on a sheet of glass above the "background" and it may be further elaborated by the use of effect lights to create highlights brighter than the background tone while the main outline of the object is darker.

Leather: (1) smooth finishes—e.g., calf—are best lighted with a combination of soft normal lighting and as much hard oblique lighting as is needed to bring out the surface texture.

(2) Grained, glossy finishes—e.g., crocodile—call for plenty of soft frontal light to reproduce the shine plus a spotlight for modelling the object. Grained, rough finishes like natural crocodile, lizard and snakeskin may be lighted normally, to show the natural pattern, or cross-lighted to show the texture. If the pattern is to show clearly, there must be no shine visible on the surface when viewed from the camera.

(3) Hide: the rough-textured "pigskin" finish is best reproduced by point-source lighting from slightly to the rear (to emphasize the texture) and as much diffused frontal lighting as is necessary to register the over-all shape and form of the subject. The glossy type of finish can be given similar treatment except that the texture lighting should be softer to give more prominence to surface reflections from the rounded pattern than to the shadows. An effect light—usually a small spot—will generally be necessary to add life and modelling.

Its position will depend upon the shape of the subject which might be a pair of gloves, a handbag, or a suitcase.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

(4) Suède: this must be carefully brushed in the direction of the pile and then given hard lighting for texture with a point source—e.g., a carbon arc—in combination with softer general lighting to show the shape of the subject and its basic feeling of limpness.

Tweed: this calls for contrasty oblique lighting—e.g., from a carbon arc spot—to pick up the texture and some soft frontal light to show the pattern. If the material is draped, it may be necessary to suggest the texture with rim lighting and devote the principal lighting to modelling the folds and recording the pattern.

Silk: a soft flood of frontal light will bring out the shimmer and gloss of the material, but an effect spotlight should also be added to introduce life and modelling and prevent the photograph from being flat and humdrum.

Paper: the lighting will vary according to the type of paper and the reason for photographing it: backlighting for translucent papers; cross lighting for rough textured papers; frontal lighting for patterned papers.

Pottery: the unglazed variety is best given normal but hard lighting to bring out the essential roughness of its texture. An effect spotlight can be usefully included to add a highlight. Glazed pottery needs soft lighting with no reflections, except possibly a catchlight, otherwise the beauty of the pattern will be obscured.

Delicate china should be given backlighting to reproduce its translucence with enough frontal light to show the shape and pattern.

Silver and polished metal ware: this generally calls for a very special technique. The basic requirement is a soft and widespread source of illumination which will form no definite reflections on the surface of the subject. The light of a flood may be "bounced" off a large sheet of white paper; the subject may be set up in a muslin tent illuminated from outside by one or more floodlights while the camera peeps in through a hole. There are various tricks for dulling the surface—e.g., with putty—to kill reflections, but these can easily destroy the real character of the metal.

Wood: wooden objects are usually finished smooth or even polished, so they have no real surface texture.

At the same time, however, the principal object of polishing is to reveal the beauty of the grain, so the grain must be reproduced in the photograph. Normal lighting for modelling is satisfactory, but the rendering of the grain can be improved by using a colour filter in front of the lens. The colour filter should never be deeper than the palest tint of the wood—i.e., a pale yellow for such woods as light oak and sycamore, a deep yellow or orange for walnut, and a light red for mahogany.

CONTRAST AND EXPOSURE

When the lighting on the subject has been arranged to give the required effect, other photographic considerations must be made; these are principally concerned with subject contrast and exposure.

Contrast. In taking pictures by artificial light, the subject contrast is completely under the control of the photographer. His principal light sets the level of the highlight illumination and his fill-in light fixes the level at the other end of the scale. It is not enough to build up a lighting scheme that gives the desired visual impression; he must know what is going to happen to the highlights and shadows when they have been translated into the corresponding dark and light grey tones of the print. How they will reproduce will be governed by his handling of the successive variables of negative exposure and development and the contrast grade, exposure and development of the print.

All this points to the need for careful records of the lighting arrangements and rigid control and recording of all the subsequent stages. Without a great deal of experience in handling subject lighting it is impossible to predict the final effect of any lighting set-up. The professional can acquire the experience fairly quickly; the amateur can avoid a lot of wasted exposures by making detailed notes of each set-up and its results.

Once the lights are in position, the contrast can be controlled by moving them closer to the subject or taking them farther away. As a starting point, the principal lighting should be three to four times as bright as the fill-in lighting. If both sources are of equal power and are broadly diffused, the fill-in light should be twice as far from the subject as the principal light. For colour photography, the fill-in light needs to be closer to give low contrast.

This basic arrangement assumes that the photographer wants to cover all the tones of the subject from the deepest shadow to the brightest highlight in an evenly graded black to white scale of tones in the print. If, however, he wishes to bunch all the deep greys together into a mass of solid black to create a special effect, while allowing the middle and light tones to reproduce normally, he can move the fill-in lamp farther away and put the subject contrast outside the range of the sensitized material. Or a similar effect may be achieved by underexposing slightly. He will then finish up with a print in which all the feebler subject brightnesses were too weak to register on the negative and thus print out dead black.

With the same lighting contrast, a longer exposure would allow the shadow detail to record normally but clog up the highlights so that they would reproduce as blank white paper. This effect is never deliberately sought as clear white paper has none of the aesthe-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tic possibilities of equally blank dark areas.

Correct adjustment of the contrast range established by any lighting set-up is just as important as the placing of the lights; unless it is deliberately planned, the appearance of the final print will be a matter of guesswork.

Exposure. There is no one "correct" exposure for any given subject and lighting arrangement. It is true that if the contrast of the lighting is adjusted so that it exactly corresponds to the gradation of the sensitized material, only one exposure value will give a faithful representation of the subject brightnesses in the print. But very often the photographer does not want a faithful representation. He may wish to compress the dark or the light tones; he may wish to produce a high or low key picture. The photographer has at his disposal a number of variables which enable him to control the appearance of the final print. Exposure is one of these and it is no more possible to lay down hard and fast rules about it than to tell a painter how he should apply his colours.

The only really satisfactory answer is to use a photo-electric exposure meter and take readings on or at the parts of the subject that are to appear fully exposed in the negative. If the subject is more or less even in tone all over, a reading from the camera position will be satisfactory, but if the important tones occupy only a small part of the picture—e.g., the face in a portrait—then the meter must be taken right up to the subject so that it sees only that part.

If the separate readings of the required highlight and shadow luminosities show that the range is too great for the material, then the lighting must be adjusted to decrease the contrast.

Frequently, however, the contrast will lie well within the range of the material, and there will in that case be a range of exposures that will give proportional reproduction of the tone values of the subject.

The normal type of photo-electric meter may not be sensitive enough to give a reading on the shadow areas even if the meter is fitted with a low-light scale. When this happens, the answer is to use a highlight reading as a basis for calculating the exposure. If, for example, the contrast range is known to be short, then the highlight reading can safely be used without risk of under-exposing the shadows.

While actual measurement with an exposure meter is the only reliable method of arriving at the exposure, there are various published tables that enable a fair estimate to be based on the set-up data.

The factors that have to be considered in using the tables are:

(1) Subject: light or dark; colour.

(2) Room: light or dark walls and ceiling; small or large—i.e., reflecting surfaces close to or far away from subject.

(3) Lights: number, power, types of reflector, distances from subject and angles at which light strikes subject; colour temperature (for colour photography).

(4) Sensitized material: speed; colour sensitivity; latitude.

The tables give an arbitrary figure to each of these factors and the total figure for each lighting set-up, subject and sensitized material corresponds to an exposure value stated in the final column.

A condensed table of this type is given below. It gives exposures for a single Photoflood bulb (or equivalent 500 watt light source) in a wide-angle, matt surfaced reflector, for fast panchromatic film. The table refers to subjects of average brightness; exposures should be doubled for dark subjects and halved for light ones. It assumes that the lamp is used in the basic modelling position—i.e., 45° above, and on the side-front of the subject with a fill-in light or reflector directed from the camera position.

SHUTTER SPEEDS

Distance of Lamp from Subject (feet)	Aperture 2	2·8	4	5·6	8	11	16	22
3	1/400	1/200	1/100	1/50	1/25	1/10	1/5	½
4	1/200	1/100	1/50	1/25	1/10	1/5	½	1
6	1/100	1/50	1/25	1/10	1/5	½	1	2
8	1/50	1/25	1/10	1/5	½	1	2	4
11	1/25	1/10	1/5	½	1	2	4	8
16	1/10	1/5	½	1	2	4	8	16
22	1/5	½	1	2	4	8	16	32

The speed for any other lamp can be calculated from its effective light output—e.g., with two Photoflood bulbs the exposure would be halved—i.e., from 1/25 to 1/50 second.

Effect of Inverse Square Law. Under certain ideal conditions it would be possible to say what change should be made in the exposure if the lights were moved closer to or farther away from the subject. According to the inverse square law, moving a lamp to double the distance calls for a four times increase in exposure; to three times the distance, a nine times increase, and so on. But in practice it is not possible to apply this rule rigidly.

First of all, the law applies only to light radiating from a point source—like the spokes of a wheel. It does not apply to the haphazard bundle of light rays thrown out by a pearl Photoflood bulb in an arbitrarily curved reflector that may be either matt, polished, or something in between. With such a light source it is possible for a proportion of the rays at either the centre or around the edges of the beam to remain more or less at the same intensity as the distance is increased while the rest of the rays fall off in intensity according to the law of inverse squares. Everything depends on the shape of the reflector, the type of bulb, and the position of the bulb in the reflector.

Then the law takes no account of reflections from other surfaces, and in practice these can contribute a great deal to the illumination of the subject. When a lamp in a reflector is close to the subject all its light may be concentrated in a hard patch of light, leaving much of the subject only weakly illuminated. If the same lamp is moved twice as far away, a proportion of the rays will then fall on the surroundings. If these are light in tone and happen to be suitably placed, they may reflect more light than before on to the parts that were only weakly illuminated. Under these circumstances it might not be necessary to give the exposure anything like as much as the four times increase demanded by the law of inverse squares.

Finally, with a spotlight focused to give a parallel beam, the law of inverse squares does not apply at all. If the beam is truly parallel, it will have the same intensity, and call for the same exposure, at 50 feet as at 5. In fact, a large diameter spot focused to give a converging beam would, up to a point, call for a decrease in exposure as it was moved farther away from the subject. This ignores though, any light loss due to dust in the air.

All this points to the impossibility of laying down reliable rules for calculating the exposure required with any given set-up. The professional worker does have a chance to standardize certain lighting arrangements and find out by trial and error the correct exposure for each. By constantly using the same lighting equipment, he can usually judge correct exposures merely by experience. But for the amateur the most reliable guide is a photo-electric exposure meter and a book of systematic notes. F.P.

LIGHTNING. Flashes of lightning are not difficult to photograph. The light of the flash is bright enough to give a good image on a medium-speed film with an aperture of *f*11. This means that a box camera can be used as well as any other type.

The camera is simply supported on a tripod and aimed at the part of the horizon where the flashes are most frequent. The shutter is set at B, held open until a flash occurs, and then released. It may also be left open long enough to record a number of flashes, but in this case each successive flash adds to the illumination of the scene generally. The landscape and clouds show up more and more clearly, and cause the lightning itself to lose intensity by comparison.

Photographing from an open bedroom window will provide a skyline of rooftops in semi-silhouette, a fitting setting for the subject. If there are distant spires or trees, etc., which can be included, so much the better.

The wider the aperture of the lens, the more the details of the scene are reproduced. It is generally an advantage for the picture to show something of the landscape and clouds, for which reason it is advisable to use an aperture of about *f*6·3 on medium or fast pan films, although a very much smaller stop will reproduce the lightning. In principle, however, most of the scene will appear as a silhouette, so the camera should be pointed at something which has a characteristic outline.

LIGHT SOURCES

The sun and the moon are the only natural light sources normally employed by the photographer. Moonlight itself is of little practical value as a light source, and is only of use for special effects. The sun is, for general photography, the most important and widely used of all light sources.

The sun is not considered in this survey of light sources since the technical considerations of natural light are sufficiently vast to be dealt with elsewhere, separately, in a number of different contexts. Since the sun is also the only useful natural light source, no alternative choice of lighting can be considered.

Apart from the sun (and sometimes the moon) the other light sources the photographer has available are those created artificially by electricity or combustion. Electric light sources are usually the more convenient to use, although at times non-electric sources of lighting may be necessary or offer some special advantage.

History. From the earliest days of photography attempts were made to take pictures by artificial light in order to shorten the exposure, and to enable portraits to be taken on dull days. The first artificial source employed was oxy-hydrogen light (limelight), used by L. L. B. Ibbetson of the Royal Polytechnic Institution, London, in 1839–40 for daguerreotypes taken with a microscope. Limelight proved too harsh for portraiture. The same applies to John Moule's Photogen patented in 1857, which burned a pyrotechnic compound, with a screen of blue glass to protect the sitter from the glare.

A more satisfactory source was magnesium wire or ribbon, the actinic qualities of which were observed by Prof. Robert Wilhelm Bunsen of Heidelberg and his assistant (Sir) Henry Roscoe, 1859. The first portrait by this light

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

was taken on 22 February 1864 by Alfred Brothers of Manchester, the sitter being Roscoe. Brothers also demonstrated its use in a Derbyshire coalmine soon afterwards. Flash-light, or magnesium in powder form, first proposed by W. White in 1865, only came into use in 1886, but smoke formation was a great drawback. In 1892–3 Chaufour designed an electric photoflash lamp of coiled magnesium wire in a glass globe, ignited by a Bunsen battery. The disadvantage was that the globe frequently burst through the expansion of the oxygen in it. This was avoided in Dr. Paul Vierkoetter's vacuum flash-bulb, 1925. The modern safety flash-bulb was born, and has been in general use since 1929 when Johannes Ostermeier substituted aluminium wire or foil for magnesium, in oxygen in a sealed bulb.

Some of the micro-daguerreotypes of medical specimens taken by Léon Foucault and published as engravings by Alfred Donné in 1845, were illuminated by a carbon arc lamp. Fox Talbot demonstrated photography by the flash of a Leyden battery in 1851. For portraiture, the carbon arc lamp powered by a Bunsen battery was experimented with by Gaudin and Delamarre in France 1854. Levitzky in St. Petersburg and Nadar in Paris installed this lighting system in their studios in 1857 and 1858 respectively. Nadar photographed the sewers and catacombs beneath Paris by the same light system in 1861–2—the first photographs ever taken underground. The first portrait studio in the world using electric light exclusively was opened in London in 1877 by Henry van der Weyde, an American. He used a 6,000 candle-power carbon arc powered from a dynamo, and a lighthouse lens in the 4 ft. reflector. Public electricity supply did not become generally available until the early years of the twentieth century.

A few provincial studios used gas lighting augmented by reflectors, one of the first being P. Maitland Laws of Newcastle-on-Tyne, *c.* 1880. The heat generated limited its use.

H. & A.G.

ELECTRIC

Five main types of electric light source are used to provide photographic lighting: tungsten filament, arc, vapour discharge, fluorescent and flash discharge. Although flash bulbs are fired by an electric current, the light they give out is produced by combustion of a magnesium mixture in the form of foil, wire, or paste, so they do not rank as normal electric light sources.

The principal variables in electric light sources are: consumption (measured in watts), total light output (measured in lumens), efficiency (measured in lumens per watt), colour temperature (measured in Kelvin degrees) and life (measured in hours).

Tungsten Filament. The light emitted by a tungsten filament lamp is produced by passing an electric current through a tungsten filament enclosed in a glass envelope (usually filled with an inert gas). The wire is heated to incandescence by the passage of the current. Light output and colour temperature depend upon the design of the filament and the applied voltage. Several types are used in photography.

First there is the ordinary domestic lamp normally supplied with a bayonet cap and a frosted or pearl bulb in powers up to 150 watts. Filament lamps of higher power are supplied with screw caps and the glass envelope is normally too large for domestic fittings.

Then there are abnormally bright lamps of the domestic type in which the extra light is obtained by over-running the filament—i.e., by applying the usual domestic supply voltage to a filament which would normally be run on a lower voltage. The result is a lamp that gives an abnormally bright light but has an abnormally short life. These lamps vary in performance and life according to the degree of overloading.

The third type of filament lamp is designed for use in projectors and spotlights. In such lamps the filaments are designed to conform to the optical requirements of the projection system and may be bunched to provide an approximate point source, or spread out to give a flat, uniformly bright grid. Size, consumption, output and method of connecting vary widely according to the type of equipment in which they are used.

A further and more modern kind is the quartz-iodine lamp which contains the filament in a narrow quartz (or high-melting glass) tube together with a trace of iodine vapour. This type of lamp may be over-run and yields a light of constant intensity and characteristics throughout its burning life (which is longer than that of normal filament lamps).

Filament lamps are suitable for both A.C. and D.C. supplies.

Arc. There are several types of arc lamp, the light in all cases being produced by the passage of an electric current across a gap between two electrodes.

The commonest type is the carbon arc lamp, with electrodes made of carbon which may be either open to the air (open type) or almost completely enclosed in a glass globe (enclosed type). The carbon electrodes may be of plain carbon run at a low current density (low intensity arc) or cored with certain metallic salts and run at a high current density (high intensity arc). Carbon arcs are used in spotlights, floodlights, and particularly for film studio lighting where the near-daylight colour temperature of the high intensity arc is welcome.

There are both D.C. and A.C. carbon arcs.

Another type of light source based on the arc principle is the concentrated source in which the current passes across the gap between two

ELECTRIC LIGHT SOURCES COMPARED

metallic beads enclosed in a glass bulb containing mercury vapour. In a third type the arc takes place in an argon-filled bulb and the light is emitted by a coating of molten zirconium on one of the electrodes. These point sources are highly efficient and are used in certain types of projector and in scientific optical equipment. They are manufactured for both A.C. and D.C. supplies.

Vapour Discharge. Vapour discharge lamps are based on the fact that an electric current passed through certain gases at reduced pressure causes them to emit light. The wavelength of the light emitted depends on the nature of the gas, and the light is produced by a phenomenon known as resonance vibration which is not necessarily accompanied by the generation of any considerable amount of heat (as occurs in filament and arc lamps).

The basic lamp of this type is the Cooper-Hewitt mercury vapour lamp, usually consisting of an evacuated glass tube (up to 6 feet long) with an electrode at each end and a small amount of mercury to supply the vapour. These lamps give an intense blue-violet light which is very actinic to blue-sensitive emulsions and is particularly suitable for blockmaking and for printing on document materials.

There are also medium and high pressure versions of this type of lamp. These tend to have a higher efficiency and are much smaller than the low pressure Cooper-Hewitt type.

The design of high pressure mercury vapour lamps varies widely; they are used in many fields of photography from small projector lamps and spotlights to high power film studio spots and floods. As the light frequencies generated are restricted to one or two sharply defined bands, they are useless for colour photography. The physical characteristics, contacts and supply requirements of such lights vary as widely as the applications.

In addition to mercury, other substances, notably sodium, are used in vapour discharge.

Sodium lamps are familiar as the bright yellow street lamps but they may also be used as photographic lighting. Other gases, such as neon, give light which has applications in fields like advertising display, but is not used in photography.

Fluorescent. Fluorescent light is simply a development of the vapour discharge principle. The fluorescent lamp is a vapour (generally mercury) discharge lamp coated with a substance that fluoresces under the action of the rays emitted by the vapour. The lamp is mostly manufactured in the form of a tube with a contact cap—usually bi-pin, bayonet or raised contact—at each end. The colour temperature of the light depends on the nature of the coating materials; most manufacturers list three colours—natural, daylight, and warm-white. A special colour-matching shade is also available.

Flash Discharge. Electronic flash tubes are another special application of the vapour discharge principle. The tube in this case is normally only a few inches in length and it is filled with a mixture of rare gases—e.g., argon, krypton or xenon. The discharge is of extremely short duration and the energy dissipated is correspondingly high; the result is a brilliant flash of light. The energy is provided by building up a charge of electricity in a condenser connected across the terminals of a main supply or a suitable battery. Some tubes are designed to flash as soon as the voltage is applied; others

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

are permanently connected across the supply terminals and flashed by applying a "triggering" voltage.

The brilliance of the flash depends on the type of tube and the quantity of electricity discharged through it from the condenser. The output is measured in watt-seconds or joules and may range from less than fifty to many thousands.

As the light is cold, intensely bright, and almost identical in colour temperature with daylight, it is widely used for flash photography, not only of moving subjects, but even for serious portraiture, copying, photomicrography, underwater photography and medical and dental photography. F.P.

Colour Characteristics. Tungsten filament lamps range in colour temperature from 2,600 to 3,400°K. The over-run lamps for colour photography—3,400°K—are suitable for type A artificial light reversal colour film. Standard studio lamps for colour photography burn at 3,200°K and are used with type B or tungsten artificial light colour film. Quartz-iodine lamps exist in both kinds, the 3,400°K ones being over-run to a greater degree than those burning at 3,200°K.

Ordinary household lamps, with their low colour temperature, are not really suitable for colour photography except with very heavy compensating filtration.

Most other light sources (arcs, discharge lamps, fluorescent lamps, electronic flash) have no continuous spectrum of uniform or uniformly varying energy distribution; certain spectral bands tend to predominate. Where the source has an underlying emission in all the main spectral bands, the colour quality can be approximately specified by an equivalent colour temperature rating. With most colour films (but not all) such sources will give results similar to those obtained by exposure by a light of the appropriate colour temperature.

NON-ELECTRIC

Non-electric artificial light sources are used in photography either because no electricity supply is available, or because of their special characteristics.

In the first case they can serve to illuminate the negative in an enlarger, the slide in a projector, the subject to be photographed, or they can be used as the light source in contact printing. In the second case they may be used because of certain technical advantages they possess.

Any artificial light source can be used for photography providing sufficient exposure is given.

Most non-electric sources are inconvenient, however, and in practice the photographer who has no electricity available only reverts to gas or pressure oil-lamps, or one of the other sources described below, because of their occasional usefulness.

PRINCIPAL NON-ELECTRIC LIGHT SOURCES

Source	Main Application	Equivalent Electric Lamp Wattage (Panchromatic Material)
Gas:		
No. 1 Mantle	General (studio lighting; enlarging; projection)	25[1]
No. 2 Mantle		40[1]
No. 3 Mantle		50[1]
No. 4 Mantle		75[1]
Acetylene: 3-jet burner	Enlarging and projection	About 200 Depends upon jet size and gas pressure[2]
Oil: Wick	Photomicrography	½-in. wick = 4, 1-in. wick = 10, large circular wick = up to 40[3]
Incandescent	General	60
Pressure	General	150–200
Candle	Special effects; calibration of photometer exposure meter	1[3]
Magnesium ribbon	Still-life; contact printing; night photography	250
Flash bulbs	Night photography; illumination of shadow areas in sunlight, etc.	Depends on bulb size. Average over duration of flash—30–200 kilowatts

[1]Varies with make and age of mantle.
[2]About two-thirds of the wattage of electric lamp giving same visual illumination.
[3]Very deficient in blue.

Gas. By this is generally meant coal-gas, consisting almost entirely of a mixture of hydrogen, methane and carbon monoxide, all of which burn with a bluish non-luminous flame. To obtain a good light the gas flame is made to heat a fragile fabric of metallic oxides (mainly thoria). This "mantle" is heated to incandescence and gives out a light approaching that of an electric lamp. The amount of light given out depends upon the size of the mantle, its composition and age, and on the gas supply.

A mixture of butane and propane is sold in cylinders for isolated houses, caravans, etc., and it behaves very much like coal-gas.

Acetylene. This is a gas unlike coal-gas in that it gives a brilliant light when burnt as a simple jet without the need of a mantle. Acetylene is normally generated by dripping water on to calcium carbide in a specially designed container and hence is a useful illuminant for portable lamps. It is little used nowadays, but some country houses have been piped for its use.

The arrangement for enlargers or projectors generally comprises three jets formed as a unit. Mixed with oxygen, acetylene gives an intensely hot jet which was used to heat a block of lime to produce genuine lime-light. This brilliant but temperamental light source was at one time popular in "magic lanterns" and for theatre stage spotlighting. It went out

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of favour when the more convenient electric arcs and filament lamps were introduced.

Oil-lamps. These take three forms: simple wick, incandescent, pressure.

The first utilizes a wick up which oil is drawn by capillary attraction and is vaporized by the heat of the flame. Carbon particles ("soot") rising from the wick in the updraught separate out by breakdown of the hydrocarbon (oil) and are then rendered incandescent—thereby providing the light source. This source is extremely deficient in blue.

The second type is designed to mix enough air with the oil vapour to give complete combustion. The flame is hotter, but no longer luminous. It has a mantle added and this becomes incandescent in the heat of burning oil vapour in a similar manner to the gas mantle.

The third type also utilizes a mantle but it is heated by gas formed from oil vapour passing through tubes preheated by the heat from the mantle flame and under pressure obtained by manual operation of an air-pump attached to the oil reservoir. In principle it is the familiar blow-lamp with the addition of a mantle.

Candle. The candle, once burning has started, functions like a small wick-type oil-lamp. The paraffin wax of which it is composed melts and the liquid is drawn up the wick to burn with separation of carbon which glows and gives out light.

Magnesium. This is an inflammable metal which is rather difficult to light due to a thin tough coating of oxide which forms on it when stored, but once lit it burns with a great heat and vivid blue-white flame more akin to the light given by a Photoflood than by a normal electric lamp. A cloud of dense white smoke (magnesium oxide) is produced; this is harmless but messy. There are also various formulae for flash powders which incorporate powdered magnesium and other chemicals.

All the above sources require oxygen to function and adequate ventilation must be provided both to supply the needs of the source and to remove fumes.

Flash bulbs. Although these are fired electrically, they can be classified as non-electric light sources because the flash is caused by combustion. The mechanics and technique of flash are, however, a normal aspect of photography.

APPLICATIONS OF NON-ELECTRIC SOURCES

Many of the non-electric light sources can be used in photography, and in specialized cases may be preferable.

Contact Printing and Projection. Contact printing may very conveniently be carried out by household incandescent oil-lamps, gaslight or any of the other sources listed above. The use of such sources presents no particular problems in contact printing; gaslight papers, now better known as contact papers, were so named because gaslight was the commonest printing light at one time.

With one or two exceptions, vertical enlargers are made for use with electric light only and cannot be adapted very easily for non-electric sources. Horizontal enlargers are easily adapted. Most models of this latter type have a roomy lamphouse sufficiently well ventilated to take illuminants such as incandescent gas, a pressure oil lamp, or an acetylene burner. A diffuser of ground glass or flashed opal must be inserted between the light source and the condenser. This prevents an image of the source from appearing in the print and avoids the need for adjusting the position of the light each time the degree of magnification is altered.

A horizontal enlarger of this design may also be used for projecting slides. The diffuser can with advantage be omitted in this case as the human eye is not very critical of uneven illumination and the degree of magnification is not so frequently changed. The light source is adjusted by first roughly focusing the projected image, next removing the slide and centralizing the light, and finally moving the source backwards or forwards to give even illumination.

A special projector for miniature slides and film strips is made by at least one manufacturer. Two models are available to take, respectively, one of two well-known pressure oil-lamps. The lamp is instantly removable when required for ordinary lighting purposes.

Subject Lighting. When taking photographs by the light from non-electric sources, exposure is the major problem. Photo-electric exposure meters can be relied upon when using panchromatic material—if the lighting is strong enough to produce a reading. Quite often, though, even the incident light method of taking a reading will not give a satisfactory indication, or the lighting may be so unevenly distributed that the reading of an integrating meter is meaningless. The correct exposure must then be found experimentally.

Orthochromatic materials are not very suitable for work with these light sources, owing to the low colour temperature which leads to an appreciable speed loss in emulsions not sensitive to red.

With coal-gas lighting, the usual exposure calculating tables may be used. A single burner fitted with a No. 1 (bijou) mantle is equivalent to a 25 watt electric lamp; a No. 2 (medium) mantle should be rated as 40 watts and a No. 3 mantle as 50 watts.

Exposures using incandescent oil-lamps may be similarly calculated on the basis of 60 watts per lamp, or for the more powerful pressure type, 150–200 watts.

Magnesium ribbon burns with a very actinic light and two pieces about four inches long, burning at 6–8 feet from the subject in an average size room, enable *f* 8 to be used for the approximate burning time of ½ second.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Owing to the relative inflexibility of non-electric lighting systems, advantage should be taken of reflectors. A large mirror or white sheet can supply, in effect, a second light source. Reflector fittings such as are used for electric lighting cannot readily be contrived, but mirrors hung or stood behind the source can increase the useful illumination on the subject.

Street Lighting. Some street lighting is still provided by incandescent gaslight, but even within the circle of light cast by the lamp, exposures of 10 seconds at *f* 2·8 (five minutes with a box camera) will be required. Lamp-posts in narrow streets and alleys can make good night pictures, especially if a figure is included and there is a wet pavement to add interesting reflections. To obtain an adequate outline of the surrounding walls an exposure of one minute at *f* 2·8 will be necessary. Anti-halo films or backed plates are essential, and a lens hood must be used to exclude all unwanted direct lights. A coated lens is a definite advantage.

If the photographer can look down on such an alley, the top shade of the lamp will screen the light source and reduce flare and halation.

Equally interesting pictures can be taken with relatively short exposures by using the twilight to illuminate the shadows. For example, an effective picture of a lamp-lighter adjusting a lamp could be obtained at dusk with ½ second exposure at *f* 2·8. Alternatively flashlight may be used to help out the street lighting so long as it is relatively subdued and does not betray itself by producing additional shadows of its own.

Firelight. A group sitting near a camp fire may be photographed by the light of the fire using a short time exposure. The size of fire, its rate of burning and the distance of the group from it may all vary so widely that it is impossible to suggest exposure times; but as there is no exact criterion for the amount of detail required, the exposure is not critical. It is best not to include the flames in the picture, although a much smaller fire arranged nearer the group may be safely included. With a ring of people around a bonfire, a very effective picture can be obtained by throwing a little flash powder—wrapped up in paper—into the fire.

The camera should be shielded from the direct flash by the people around the fire.

Weak Light Sources. Matches, candles, etc., can be used successfully in making a picture, but the occasions when they constitute the only source of photographic lighting are rare.

With one candle at 15 ins. from a person's face, and a second at 3 feet distance, an exposure of 20 seconds at *f* 2·8 is ample. And since the intensity of light varies inversely with the square of its distance from the source, the exposure may be shortened by bringing the light closer to the subjects. With two candles at about 12 ins. from the subject, a well-exposed negative can be obtained in 1 second at *f* 2·8 (30 seconds with a box camera). Screens must be used if the candles are not to appear in the picture; if included, they must be close to the subject or they will appear unnaturally bright by comparison with the illumination of the subject.

A lighted match held at the end of a cigarette will light the face characteristically and produce an interesting portrait. The match should be struck upwards and the camera shutter opened immediately the match is at the cigarette end and while the actual head is still burning. Both the subject and the camera must be kept steady while the match head flares up; the shutter should then be closed. An aperture of *f* 4·5 should be used with a fast panchromatic film.

An excellent detailed picture of an ordinary open type fireplace may be obtained by the light of the burning coals in about half an hour at *f* 3·5.

Ultra-speed Films. All the above exposure suggestions are based on a medium speed film of 80 to 160 ASA. Materials of extreme speed (800 ASA or more) permit even hand-held instantaneous exposures at full aperture (1/15 to 1/30 second), especially when processed for maximum emulsion speed.

Infra-red. Infra-red radiation for photography is normally obtained electrically, but, using special infra-red film, pictures can be taken in the dark by the "light" from a hot stove or even a couple of hot flat-irons. As lenses are not normally corrected for infra-red, the change in focus must be borne in mind. Some cameras have an auxiliary focusing index for infra-red work. An approximation may be found by focusing visually on a ground-glass screen with a tri-colour red filter over the lens, or the lens may be moved forward about 1/250 of its focal length.

Specialized Uses. Certain non-electric light sources are valuable in their own right for technical reasons. The modern wax candle and nightlight are very consistent and steady in their light output, and one make of photometer exposure meter is intended to be calibrated against such a source. Another valuable source is the wick type oil-lamp which finds wide application in photomicrography of fine detail.

Its steady flame is virtually structureless and can be focused in the plane of the microscope slide without contributing extraneous detail to the final image. R.E.

LIGHT SOURCES IN THE PICTURE

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Although camera owners are often advised to have the light coming from behind or from one side of them, many effective pictures can be secured by deliberately including the light source in the photograph.

With the camera in this position, however, the full strength of the light will be falling on the lens. Special care is therefore called for to avoid diffusion, fogging and flare in camera and lens; and special exposure and processing techniques are required.

Avoiding Reflections. The internal condition of the camera is important. All metal parts and also the surfaces of fabric bellows should be totally non-reflecting. This is true for general photography, of course, but when shooting directly into the light there must be absolutely no possibility of internal reflections degrading the negative. Similar attention should be given to the lens mount and to the interior of the lens hood, both the often unsuspected cause of veiled negatives.

Cleanliness of the lens is also of prime importance. The slightest deposit of dust on any of the surfaces will result in veiled negatives. There will also be the risk that a brilliant source of light will introduce reflections between the components of a lens and cause circular flare patches to appear in the negative. In addition, fogging can be caused by light scattered within a lens. To a certain extent, and depending upon the design of the lens, use of a coated optical system will help to prevent such troubles.

A lens hood should always be used for taking photographs into the light. It may at first seem incongruous to try and shield the lens from a light source that is intentionally pointed at the lens; there is, nevertheless, the possibility of reflections arising from surfaces outside the picture area. Indoors, these may well come from mirrors or the glass of framed pictures. Even the highly polished surface of a door or table top can reflect sufficient light into the lens to reduce the brilliance of a negative. Out of doors, reflections may come from shop windows, car bodies and windscreens and from puddles.

Reducing Contrast. With the light source occupying a prominent position in the picture, other parts of the subject will be in shadow and this excessive contrast is perhaps the greatest danger with this form of photography. The ideal method of overcoming this hazard is by using a *shadowless* fill-in floodlight to bring the level of the general illumination up to the required brilliance. Note the accent on shadowless. This is important because in practically all pictures in which a light source is included the effect desired is for this to be accepted as the only light. For example, a still-life subject of a book, spectacles and oil lamp or a candle would be entirely ruined if the appearance of shadows made it obvious that the scene was lit, not by the candle or reading lamp, but by studio type floodlighting; the effect would at once be artificial.

For all indoor photographs in which table lamps, candles, matches are included, it is a simple matter to provide this over-all fill-in illumination with either diffused flash or diffused floodlight. An effective method of doing this is by turning the reflector towards the ceiling. When working out of doors the prevailing conditions have to be accepted and steps should be taken to reduce the excessive contrast by employing a modified form of processing. It is also possible to secure softer negatives by exposing at dusk.

Exposure. As with all forms of photography, calculation of the exposure is of the greatest importance. It is obvious, however, that in this case normal methods of estimating exposure cannot be employed. If, for example, the exposure were to be calculated from the brilliance of the light source the surroundings would be considerably under-exposed; conversely, if the rule "expose for the shadows" were obeyed, then the light source would be hopelessly over-exposed. Therefore, it is necessary to strike a balance between the two extremes that will produce the desired result, bearing in mind the main point of interest.

Although for street scenes at night the fastest film should be used, for still-life sets indoors it is advisable to employ a medium speed plate or film. This is because the slower emulsion is likely to give a more evenly balanced result with detail at both ends of the scale than super-speed emulsions.

Processing. With high contrast being the chief feature of against-the-light photography, processing must be controlled to avoid increasing this contrast further with the resultant loss of detail. A good negative of a candle picture—or for that matter any photograph in which a light source is deliberately made the centre of attraction—should show detail in all areas, even in the flame or lamp filament. Generally, it is sufficient if the normal developer is used but with the time of immersion reduced to about two-thirds of that usually given. For some subjects, however, it may be necessary to resort to a soft working developer.

The Sun. The sun itself can be included in the field of view when it is suitably filtered through thick mist or fog. If using an integrating exposure meter, take one reading facing the sun and another away from it; then choose a compromise exposure so as to obtain any detail desired in the darker parts of the picture.

In bright weather fine pictorial effects are obtained by photographing the reflection of the sun as seen on a sheet of water. Contrasts here will be high, and shadow detail will probably have to be sacrificed.

Sunsets are not difficult to photograph pro-

CC-0. Agamnigam Digital Prestvation Foundation, Chandigarh

vided care is taken to expose while the sun is partially veiled by cloud. Best results are obtained when there is plenty of thin cloud and during the last thirty minutes before the sun actually sets. Using fast panchromatic film and no filter, an exposure of 1/100 second at *f* 16 or *f* 22 should produce a satisfactory result, but it is impossible to give a definite figure because the intensity of the light is constantly changing. If a meter reading is taken this can usually be halved.

A suggested exposure for colour film of speed 50 ASA is 1/50 second at *f* 11. The ideal method of working is to make three test exposures at three different apertures. A useful range would be 1/50 second at *f* 8, *f* 11, and *f* 16.

The Moon and Moonlight. With a cloudless sky, a full moon can be included in the picture with an exposure of about 1 second at *f* 2 using the fastest panchromatic film. Best results are secured when overlooking water so that the path of reflected light can be included.

Landscapes can be taken by moonlight, but in this case the moon itself should not appear in the picture because the long exposure necessary would show it as a blur owing to the relative movement of moon and earth. On a clear night with a full moon an exposure of 20 minutes at *f* 4·5 on fast panchromatic film should secure detail in all but the darkest objects. The movement of the moon and the long exposure make it impossible to render sharply defined shadows.

To photograph the moon itself a telephoto lens is necessary because with a lens of normal focal length the image will be extremely small. Exposures for a full moon in a cloudless sky, on the fastest panchromatic film, range from 1/5 second at *f* 3·5. Long exposures are impracticable because the moon then appears in the negative as an elongated blur of light.

Interiors. The pictorial effect of interiors is often enhanced when part or all of the normal room lighting is included in the field of view. This lighting often takes the form of a shaded standard or table lamp. If the domestic bulb is used in the lamp, the general level of room lighting will have to be low, otherwise the contrasts will be insufficient and the effect will be lost. The alternative solution is to replace the ordinary bulb by a Photoflood, keeping the over-all room lighting at a moderate level.

Assuming the light source to be included in the picture is shaded, contrast should not be excessive; but it is advisable to take exposure meter readings on the light source (as it will appear in the picture) and the main subject area, choosing an exposure that will ensure that the former is not "burnt out" while sufficient detail is retained in the latter.

Fires and Firelight. Effective photographs can be secured of groups around the fire. These are of two types: those showing the actual flames and those showing the effect of firelight.

To include the flames in the picture, a large aperture lens is necessary and with fast panchromatic film exposures need to be about ½ second at *f* 3·5 with one Photoflood directed at the ceiling to provide over-all diffused illumination.

The effect of firelight can be simulated by placing a floodlamp in the fireplace and combining this with general illumination as above. In this case exposures can be much shorter—about 1/20 second at *f* 4·5—or alternatively, flash bulbs can be used: one in the fireplace and one aimed at the ceiling. If the fireplace appears in the picture, a person or piece of furniture should be placed between the lamp and the camera to prevent the direct rays of the light from reaching the lens. Processing should be controlled to avoid excessive contrast.

Candles and Matches. Excellent photographs can be made of lighted candles as, for instance, on a Christmas or birthday cake, at *f* 4·5 on fast panchromatic film with an exposure of 1/2 second. To avoid movement of the flame the subject should be well screened from draughts and no movements made in the room immediately before exposing.

Because modern plates and films have an anti-halation coating on the back to prevent the spreading out of brilliant lights in the image, it is almost impossible to secure the attractive glowing halo as pictured by artists. To record this halo unbacked plates should be used. For a picture of a man lighting a pipe with a match an exposure of about 1/5 second at *f* 3·5 with fast panchromatic film should secure detail in the flame and in the face.

The suggested exposures given above are for use when candles or matches form the sole light source. A useful reduction of contrast, without loss of realism, can be obtained by using diffused fill-in illumination, but this must be shadowless.

An alternative method, of particular benefit to those who do not possess wide-aperture lenses, is to use concentrated artificial light, e.g., a Photoflood in reflector, or small spot, so placed as to shine from the same direction as the candles or matches. Exposures can then of course be much shorter, or smaller apertures can be used.

Fireworks. Any camera from humble box to expensive miniature can be used for photographing fireworks. All that is necessary is to have the camera on a firm support and to point it at the part of the sky where rockets are bursting and to keep the shutter open while the show lasts. The more bursts included on one film the more effective will be the result. A fast panchromatic film should be used. Catherine wheels and roman candle type fireworks make attractive pictures if the shutter is left open for about five seconds. When long exposures are given care should be taken to avoid including people in the foreground.

Street Scenes at Night. A large aperture lens is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

essential for photographing street scenes at night to allow a short exposure to be given which will stop movement. A brilliant subject like Piccadilly Circus can be recorded with an exposure of 1/20 second at *f* 3·5 on fast panchromatic film. For less brilliant scenes a short time exposure can be given with the camera on a rigid support, but the lens should be covered while cars are passing or their lights will be recorded as white lines. Street scenes at night after rain make attractive studies. The camera should be kept dry and the lens protected from raindrops and splashes. A pocket torch is a help when setting controls. As long as they keep moving pedestrians will not be recorded during long exposures.

Street lamps included in the field of view will inevitably cause halation. With larger negative sizes this can be reduced by physical abrasion, but a little can safely be left to give the impression of a shining source.

Modern highway illumination often employs sodium or mercury lamps. With a rigid tripod and the fastest panchromatic film, any type of camera may be used. Lamps near the camera should be screened from the lens by a tree or sign. Exposures range from about 45 seconds at *f* 11 for sodium lamps and about 5 seconds at *f* 11 with mercury lamps.

Illuminated Signs. Almost any camera can be used for photographing illuminated signs provided a rigid support is used. Flashing signs which tell a pictorial story progressively can be fully recorded only by keeping the shutter open for one complete sequence. Moving traffic and pedestrians cannot therefore be included. On the fastest panchromatic film exposures range from about 1/50 second at *f* 3·5.

Double Exposure. When the actual unshielded source of light is to appear in the picture it will be much brighter than the scene it illuminates. So the problem is to give an exposure that will be sufficient for the detail in the scene, but not too much for the light source. The lighting contrast is usually much greater than the latitude of the emulsion, so it is not possible to give a single exposure that will include both the source and the rest of the subject. But it is often possible to solve the problem by giving two exposures, a short one for the source and a longer one for the surroundings. The source is switched off during the second exposure, during which the scene is lit by some other suitable source, outside the picture area.

In a picture including a lighted candle the camera is set up on a tripod and the first exposure is made with the candle lighted. For this, a time of 1/25 second at *f* 5·6 on fast panchromatic film may be about right. The candle is then blown out and the subject is lit by a diffused even lighting that casts no definite shadows. The second exposure is then given to register the details of the rest of the scene. This exposure will vary according to the strength of the lighting.

The same principle can be applied to outdoor scenes including street lamps or other forms of public lighting. In this case the camera is set up on the tripod in daylight. Some time before the lamps are switched on, and while there is still some daylight remaining, the first exposure is given. This must be long enough to register a fairly thin image of the scene. The shutter is then closed and the camera left in the same position until after dark. A short exposure is then given with the lights switched on and the resulting negative shows the lights and just enough detail in the scene to complete the picture.

The moon calls for special treatment. If a moonlit scene is given a long enough exposure to show the landscape, the moon, because of its movement in relation to the earth, appears as an elongated patch of white paper. The answer is to give an initial exposure long enough to record the details of the landscape, arranging the picture so that the moon is just off the edge throughout. At the end of the first exposure, a mark is made on the focusing screen where the moon is to appear. The camera is then moved so that the image of the moon coincides with the mark, and the second exposure is given. This is just long enough to record the image of the moon without blur. The position chosen for the image in the picture should be reasonably close to the actual position of the moon during the first exposure or the shadows will appear unnatural. And as the moon always looks unnaturally small in a photograph, it is an advantage if the image can be recorded with a 2× or 3× telephoto lens while the landscape is photographed with a normal lens. LIGHT SUPPORTS. Fixed lamps are used only in some commercial portrait studios where every subject is taken with the same basic lighting. Most other branches of photography call for some form of mobile, adjustable lamp support.

Designs vary considerably, especially on the matter of adjustable joints for reflectors. However, most supports can be classified as follows: clamp holders, collapsible stands, heavy duty stands, booms, and ceiling fittings.

Clamp Holders. The clamp-on type of lamp support is particularly convenient for the amateur worker. It is simply a bulb-holder and reflector fitted to a powerful spring clamp with jaws that can be opened with a scissors action

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LAMP HOLDERS AND SUPPORTS. Left: *Examples of lamp bases.* A, *clamp-on unit.* B, *tripod (used with light telescopic stands).* C, *studio base with ball-bearing casters and movable low-angle bracket.* Centre: *Methods of lamp adjustment.* D, *flexible arm; universally adjustable, but not very rigid.* E, *hanging fitting for flood lamp.* F, *pivoted support for spotlamp.* G, *hinged arm; may be clamped at any angle.* Right: *Range of movement of individual light sources on stands.* H, *arm on column; provides vertical and angular adjustment.* I, *hinged arm providing lateral adjustment.* J, *boom light for top and under lighting; keep the light stand itself well away from the subject.* K, *twin unit with sources adjustable in any position to each other.*

and clamped on to any convenient object—e.g., the seat or back of a chair, the edge of a table, a book shelf or curtain rail. A clamp of this sort provides a cheap substitute for an adjustable stand; it takes up less room and is often more rigid.

Collapsible Stands. The simplest support is a small metal base with a stem to which the lamp reflector is attached by a universal joint that can be clamped by a butterfly nut to hold the reflector at any desired angle; alternatively, a swan-neck tubing may be used. This type of support has little or no adjustment for height, but it can be placed on the floor, a chair, a table, or even hooked on to the picture rail.

For regular use the reflector and adjustable clamp are obtainable mounted on a telescopic tube with a collapsible tripod stand. This type of unit gives height adjustment from about three to eight feet from the ground. Such supports are steady enough for Photoflood bulbs in light aluminium reflectors.

Heavy Duty Stands. Stands to hold high power studio lights and spotlights need to be of heavier calibre than the collapsible stand. The base is a substantial cast ring or spider mounted on heavy duty castors and broad enough to prevent the unit from being accidentally pushed over even when fully extended.

With the exception of lightweight collapsible stands for single Photoflood bulbs, most studio lighting stands are mounted on wheels which allow the lamps to be easily pushed into position or cleared out of the way when they are not wanted.

Booms. It is not always convenient to have the light vertically over the base of the support. This is avoided by using a cross-arm or boom, clamped to the centre pillar of the support and holding a lamp and reflector unit at the end; the other end is usually counterbalanced. The boom enables the lamp to be brought close up to the subject or even over it, while the stand itself can be kept out of the way.

Ceiling Fittings. The ceiling provides a convenient support for fixed-position lighting units. In commercial and portrait studios it is customary to suspend banks of floodlights from the ceiling for providing general illumination of the subject area. The whole bank may be controlled by a dimmer or by switching some of the lamps off, and the assembly may be counterweighted to allow it to be raised and lowered. Ceiling units have the merit of eliminating stands and trailing cables and the disadvantage of being fixed.

One type of lamp support makes use of the ceiling to hold the stand firm. The column of the stand has a circular pad at the top and bottom and it is simply extended and braced between the floor and ceiling with a quick-release toggle device. Once the column is fixed

in position it will support a reasonably heavy lamp and reflector without any risk of toppling over. This arrangement permits the lamp to be held anywhere between floor and ceiling level; it can be moved about the studio, and it eliminates the usual heavy, space-monopolizing stand. F.P.

LIGHT TRAP. Opening in a wall or partition shaped so that no light rays can pass through from one side or the other.

Rooms. Many darkrooms—particularly in busy press offices, commercial photographic establishments and hospitals—have light trapped entrances so that the staff can pass freely in and out while sensitized materials are being handled. Windows and ventilation holes in the darkroom are also fitted with light traps.

Light traps for these purposes consist of a passage incorporating an angle or bend shaped so that all rays of light coming directly from the source are blocked by the walls. This does not prevent light from leaking around the source by repeated reflection from the walls of the trap, so it is essential for all surfaces to be painted with a dead black paint that will prevent light scatter.

The simplest form of light-trapped darkroom entrance is a thick curtain hung right across the door. Anyone entering closes the door before drawing the curtain to one side and going into the room. This arrangement relies on the co-operation of the person entering for which reason most professional darkrooms have permanently baffled or shaped entrances.

Lamphouses. The ventilation passages in the lamphouses of enlargers and projectors are light trapped to prevent the light source from shining through into the room.

Lamphouse light traps usually consist of a ring of holes in the body of the lamphouse masked by a baffle carrying the equivalent number of holes placed so that there are no direct paths from the source into the room. Dead black paint on the inner surfaces absorbs any reflected light.

Ventilators. Another kind of light trap, very essential in darkrooms, is the ventilator type. This must be capable of supplying the room with fresh air (and allowing the exit of stale air) without admitting any light.

Generally the ventilator is included in the black-out arrangement of the windows—e.g., a hole in the black-out is light trapped by staggered wooden slats that overlap each other. At least one commercial make of window black-out incorporates this system.

Special light-trapped electric fans are also made for maintaining fresh air supplies in darkrooms. The fans are designed to fit snugly into a circular hole in the window black-out.

Sensitized Material Containers. A different type of trap is incorporated in holders for sensitized materials—e.g., plate and cut film holders, film packs and cassettes. In the holders for plates and flat film, there is always a slit to accept the dark slide, while in cassettes there is a slit through which the film leader projects. These slits are sealed by strips of black velvet or fabric.

In time, the light seals on re-usable equipment tend to lose their resilience and allow light to leak past. When—or preferably before—this happens, it is easy to strip off the material and glue a fresh piece in place of it.

The velvet light seals on the consumable type of film cassette cannot be renewed without pulling the case to pieces. These cassettes are not, however, intended to be used more than once; they are frequently reloaded without giving trouble, but the velvet of the light seal is apt to pick up dust and grit which may leave scratches along the whole length of the emulsion. Reloadable cassettes are designed so that when the camera is closed over them the light seal springs open and does not rub the film.

LIGHT UNITS

The units used for measuring light may be divided into those for measuring its colour or quality and those for measuring its strength or intensity.

COLOUR AND QUALITY

Pure spectrum colours are usually denoted by their wavelength. The wavelength of electromagnetic radiation may be expressed in any convenient units of length. Various other units are also used to measure colour quality.

Wavelength. Radio waves are usually measured in metres, but for visible radiation (light) the metre is much too big a unit so the millionth part of a metre is ordinarily employed. This unit is called the micron, and is written μ. Even this unit is inconveniently large for some purposes and the thousandth part of it (or millionth part of a millimetre) is commonly used. This is the millimicron, written mμ. Another unit ten times smaller is also often used. This is named after the Swedish physicist Angstrom, and is written A. Thus, the wavelength of a certain red, for example, may be denoted as 0·6438μ, 643·8mμ, or 6438A.

Colour Temperature. Pure spectrum colours are exceedingly rare in practice, however, and the near-white colour of lighting usually encountered in photography is more conveniently specified in terms of the temperature of a perfectly radiating body giving out light which matches that under consideration. Colour temperature is measured in degrees Kelvin

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LIGHT UNITS. A, luminous intensity or candle power, which is the amount of light emitted in all directions by a candle made to standard specifications. B, light source of one candela. C, luminous flux; the unit is the lumen which is the light received by a unit area at unit distance from a source of 1 candela. The total emission of this source is thus 12·57 lumens. D, illumination, which is the luminous flux per unit area and is measured in lux (lumens per square metre) or lumens per square foot (previously known as foot candles). E, reflectivity or reflection factor, which is the proportion of the incident light reflected by a surface. F, luminance or intensity of light reflected by a surface. Measured in nit (candelas per square metre) or in foot lamberts. A perfect diffusely reflecting surface (reflectivity 100 per cent) illuminated by 1 lumen per square foot will reflect 1 foot lambert; illuminated by 1 lux it reflects 1 nit.

which have the same magnitude as degrees Centigrade but are based on absolute zero (−273°C.) instead of the melting point of ice.

QUANTITY AND INTENSITY

Units of quantity and intensity of light cannot be put on an absolute physical basis because of the psycho-physiological factors involved. The units used depend upon the conditions under which measurement is being considered.

At different times and in different countries various terms and units have arisen which have never been satisfactorily nor thoroughly standardized. Hence the reader will find considerable variation of nomenclature in literature dealing with light. Preference is here given to those terms adopted by the International Commission on Illumination, but reference is made to other popular or well-established terms. The table provided below compares these and also some more obscure terms that may be met with. (The International Commission on Illumination is generally known by the abbreviation C.I.E., for the official French name Commission Internationale de l'Eclairage. The initials of the translated name, I.C.I., commonly used in America, are deprecated because they conflict with a well-known British trade-mark and because the initials of the name translated into other languages are different.)

There are four basic concepts of particular interest in photography. These are: the power of light sources; the intensity of light falling on a subject; the intensity of light reflected from a subject; and total light energy emitted or received.

Direct use is made of these concepts, respectively, when determining exposure by: the use of calculating tables involving lamp powers and distances; the incident-light method with a photo-electric meter; the common reflected-light technique using an integrating photo-electric meter, photometer, or other light meter; the use of flash bulb data, and also for test strips and plotting characteristic curves.

Knowledge of light units is not essential when making exposure measurements using empirically calibrated meters, and the photographer may never need to work out in actual figures the relation between lumens, foot lamberts, candelas, etc. But a knowledge of the basic principles underlying photometric units is always of value.

Power of Light Sources. The international standard of light emission was originally based on a specified wax candle burning under specified conditions. Hence the term candle power arose and the unit was called the international candle.

Candela: today, the international unit is the candela. It is of such magnitude that the luminance of a perfectly radiating body at the melting point of platinum is 60 candelas per sq. cm. This standard was proposed by the United States in 1936 and has now been adopted because it can be more accurately reproduced than the standards heretofore in use (i.e., the wax candle and special lamps).

Candle power: this is now defined as the light-radiating capacity of a source in a given direction in terms of the luminous intensity expressed in candelas. For all practical purposes the candela is the same as the international candle, from which it differs by less than 2 per cent.

Candle: in the Unites States the use of the term candle is being continued and it now applies to the new unit as defined above; if distinction is necessary the terms new candle and old candle are used.

Luminous flux and lumen: the luminous flux or light flow that falls on 1 square foot of surface 1 foot away from a point source of 1 candle power is called the lumen. If a uniform point source of 1 candela is placed at the centre of a hollow sphere of 1 foot radius every square foot of the inside of the sphere—and there are 4π (12·57) of them—will receive 1 lumen. Thus a uniform source of 1 candela emits 1 lumen per unit solid angle and provides a total luminous flux of 12·57 lumens.

Mean spherical candle power: the light-giving power of a lamp has been commonly expressed in the past in terms of mean spherical

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

candle power (M.S.C.P.). This is the average value of the luminous intensity in all directions and when multiplied by 4π (12·57) gives the total lumens supplied by the lamp. The average luminous intensity in all horizontal directions from a source (mean horizontal candle power or M.H.C.P.) is sometimes used when no light is radiated over a substantial angle (such as in the usual incandescent gaslight fitting) and where the M.S.C.P. would not, therefore, give a fair representation of the useful luminous intensity.

Efficiency (lumens per watt): the efficiency of an electric lamp has been quoted in the past in watts per candle power. This is responsible for the name "half-watt" being applied to tungsten lighting—from the rather optimistic estimate of efficiency of ½-watt per candle power. Actually this efficiency is only attained by over-run lamps (such as class A1 projection lamps). Lamp efficiency is now expressed in lumens per watt. If all the power supplied to an electric lamp were converted into white light the maximum theoretical efficiency would be about 220 lumens per watt. Fluorescent lamps have been made to supply up to 70 lumens per watt. A normal 100 watt lamp has an efficiency of 15 lumens per watt, which means that only 7 per cent of the energy supplied is obtained as light—the remaining 93 per cent is wasted as heat! Even a Photoflood has only double this efficiency. The practical photographer thinking in terms of 500 watt spots or 2 kilowatt broadsides is completely ignoring the many factors that intervene between the input of current to his lamps and the reception of light by his lens. To bridge this gap we must now consider the further concepts listed above.

Intensity of Light Falling on a Subject. A point source would cause exactly the same amount of light to fall on 1 square foot of surface situated at a distance of 1 foot as would fall on 1 square metre at a distance of 1 metre. Each subtends unit solid angle at the source and if the source is of 1 candela each receives a luminous flux of 1 lumen. But in one case the luminous flux is spread over a square foot and in the other it is spread over a square metre. Since 1 square metre equals 10·764 square feet, the illumination in the first case will, therefore, be 10·764 times that of the latter.

Lux, lumen/square foot and foot candle: the illumination on a surface at 1 metre distant from a point source of 1 candela is, of course, 1 lumen per square metre. This is the international unit of illumination and is called the lux. The illumination at 1 foot from a source of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

1 candela is 1 lumen per square foot (10·764 lux) and this is the popular British unit. It was previously known as a foot candle. General room lighting for reading and writing is usually of the order of 5 lumens per square foot.

Luxon: the luxon is a special unit used in considering light within the eye. It is the illumination on the retina produced by viewing a surface having a luminance of 1 candela per square metre when the pupil area is 1 square millimetre. This unit was originally termed the photon, which term now has a quite different application (see below).

Intensity of Light Reflected from a Subject. Luminance, or surface brightness, depends upon the power of reflection of a surface and must not be confused with the preceding concept of illumination, which is simply a measure of the incident light.

Nit and foot lambert: the international unit of luminance is the nit which is 1 candela per square metre. A common British unit, however, is the foot lambert which is defined as the luminance of a uniform diffuser emitting 1 lumen per square foot.

Reflection factor: the reflection factor of a surface is the ratio of the luminous flux reflected to the luminous flux incident; it is always less than unity.

Luminance factor: the luminance factor of a surface is the ratio of luminance to illumination. It always refers to specified conditions of illumination and angle of view. The luminance factor may greatly exceed unity in certain directions. For example, with 10 lumens per square foot illumination, a glass-beaded screen may produce a luminance of 50 foot lamberts when viewed from near the projector axis (i.e., luminance factor = 5) but less than 5 foot lamberts from more than 30° (i.e., luminance factor = ·5 or less).

Candelas per unit area: many light sources being extensive in area cannot be considered as point sources and the concept of luminance is also applied to them. Such high intensity surfaces are usually measured in candelas per square inch.

Luminosity: the term brightness is preferably avoided because of possible ambiguity due to the very broad meaning of the term in its popular non-technical use. It may be used in non-quantitative statements, but refers to the visual sensation and not the photometric quantity. The international term is luminosity. Thus the luminance of a surface may be doubled yet it would be permissible to say that the luminosity (or brightness) had not doubled since the sensation called brightness is generally judged not to be doubled.

Total Light Energy. Lumen second: luminous energy or quantity of light is measured in lumen seconds, also known as lumergs. One lumen second is the quantity of light given out in 1 second by a source generating 1 lumen of light power. This unit is used when considering the light given by a flash bulb. 1,000 lumen seconds is mathematically the same as 1 lumen shining for 1,000 seconds or 10,000 lumens for one-tenth of a second. In photographic practice this relationship is modified by the reciprocity failure of sensitive materials. Flash bulbs may be accurately compared by their total light output when considering open-flash technique, but not when using them synchronized with high shutter speeds since two bulbs having the same output in lumen seconds might have quite different durations of flash, and hence different peak flux in lumens.

Lux second: the lumen second may also be used when dealing with the effect of light falling on a surface for a measured length of time (photometric exposure) but the surface-area must also be specified. For this purpose a more convenient unit is the lux second which is one lumerg per square metre.

Photon: the photon is the quantum or smallest quantity of light energy that can be emitted or received. It is inversely proportional to wavelength and the photon of ultra-violet light is twice the magnitude of that at the red end of the spectrum. It is of importance in theoretical physics but of no direct practical utility. R.E.

See also: *Illumination; Light sources.*
Books: *Photometry*, by J. W. T. Walsh; *Principles of Illumination*, by H. Cotton (both London).

LIGHT VALUE. Generally, this is a term applied to arbitrary numbers assigned to subject and lighting conditions in exposure tables and some exposure meters.

Many exposure tables tabulate separately the various exposure conditions (time of day and year, weather, subject, film speed, etc.). Each set of conditions carries an arbitrary number; these numbers are added up to give a light value which is referred to a final table from which the correct exposure is read off.

Exposure values, as used on shutters, are also frequently referred to as light values.

See also: *Exposure value.*

LINE BLOCK. Photomechanical printing block consisting of a thin metal (usually zinc) plate in which the non-printing areas around the image are etched away, leaving a raised printing surface corresponding to the original image. There are only two possible tones in a line block: the full intensity of the ink, and the unprinted areas of the paper. There is no gradation in the tones of a line block impression. Line blocks are used for reproducing diagrams and black and white originals; they are not suitable for reproducing photographs and originals in continuous tone.

See also: *Photomechanical reproduction.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LINE COPY An original document or drawing consisting essentially of two tones (or black and white) without intermediate tones.

LINE OF BEAUTY. Term originally used by the English artist, William Hogarth (1697–1764), to relate gracefulness to a curved S-shaped line. He discussed it in his essay, *Analysis of Beauty*, and employed its snake-like form in some of his paintings. It is one of the elements of picture construction sometimes used by photographers who try to compose their work in the manner of academic painters.

LINKED RING BROTHERHOOD. A secession from the Photographic Society of Great Britain in 1892, under the leadership of A. Horsley-Hinton. The Linked Ring included all the younger pictorial photographers of note: George Davison, J. Craig Annan, Frederick H. Evans, Alexander Keighley and others.

LIPPMANN, GABRIEL, 1845–1921. French physicist, professor at the Sorbonne. Originated the interference method of direct colour photography (1891), which produces fixable, accurate and excellent colour photographs but is difficult to carry out. Received the Royal Photographic Society Progress Medal in 1897 and the Nobel Prize in 1908. Suggested the lenticular film method of additive colour photography.

LIPPMANN EMULSION. Sensitive emulsion containing very little silver halide in extremely fine grains so as to be practically transparent. It is characterized by almost complete absence of any scattering phenomena, and was used by G. Lippmann (1845–1921) for his colour process.

LIPPMANN PROCESS. Obsolete method of making pictures in natural colours invented by Professor G. Lippmann. The interesting feature of this process was that the colours were produced without using either dyes or pigments; they were the result of the interference of the light rays forming the image. (Interference is the effect responsible for the familiar colours in an oily film on the surface of water).

Lippmann took his pictures on a panchromatic plate with its emulsion surface facing away from the lens and in contact with liquid mercury. Light rays passing through the emulsion were reflected back by the mercury. The reflected rays interfered with the incident rays and formed a latent image which varied in depth according to the colour (wavelength) of the rays.

When this image was developed and viewed at a particular angle in contact with the surface of a mirror a faint picture was visible in natural colours.

The technical difficulties of the process are immense, and no one has succeeded in carrying it beyond the stage of a scientific novelty.

LITERATURE ON PHOTOGRAPHY. Bibliographies of specialized photographic literature can be found in numerous publications.

The subject catalogue and supplement of the Royal Photographic Society's library list books and pamphlets in the library up to the year 1952. Many of them are in foreign languages. The catalogue has about 180 subject classifications, with an alphabetical index.

Proceedings of the Centenary Conference 1953 of the Royal Photographic Society include a section which deals with 82 contemporary books on various applications of photography.

The *Periodicals Catalogue* of the Royal Photographic Society covers periodicals in the Society's library up to the end of 1955. These include all important British and American journals and many in foreign languages.

The *British Journal Photographic Almanac* publishes an abridged list of text books covering most general and certain special fields of photography. It mainly confines itself to current books, but also carries a limited selection of older publications.

Progress in Photography Volumes I (1940–50), II (1951–54) and III (1955–58) give an international survey of discoveries and new techniques in the field of photography for the years covered. Bibliographies are appended to most of the articles.

This publication was continued in 1959 as a quarterly review entitled *Perspective*, containing news of progress in photography, cinematography, sound and image recording.

The Library Association of Britain has published two guides to photographic literature. *Some Tools for Reference and Information Work in Photography* (1953), by R. S. Schultze, covers some fifty reference works, arranged according to type of publication. *A Reader's Guide to Books on Photography* (1954) applies only to British books and American books published in Britain. It includes many of the more elementary books, but also has an advanced section, *Special Applications and Subjects*.

The Society of Chemical Industry's Annual Reports on the Progress of Applied Chemistry include a section, *Photographic Materials and Processes*, which has a comprehensive bibliography on photographic work from the chemical point of view.

In the United States, the catalogue of the Epstean Collection, *A Catalogue of the Epstean Collection on the History and Science o, Photography and its Applications especially to the Graphic Arts*, now in the library of Columbia University, covers books up to 1937. Over 1,400 titles are listed, grouped in 84 categories.

An article, "Photography's 100 Best Books", was published in the November, 1954, issue

CC-BY. Agamnigam Digital Preservation Foundation, Chandigarh

of *Photography* (U.S.A.). It gives a brief indication of the scope and standard of each title mentioned. The books quoted are mostly English or American, with a few major works in other languages.

The *Photo-Lab-Index* (U.S.A.) contains *A Guide to the Literature of Photography and Related Subjects* (1943) by A. Boni. It lists 3,000 books, pamphlets and articles in journals, drawn from various countries. They are listed alphabetically by author and subject.

The periodical literature of photography is covered by three abstracting journals: *Photographic Abstracts* published by the Royal Photographic Society, *Science et Industries Photographiques* (Photographic Science and Industries) (France), and *Abstracts of Photographic Science and Engineering Literature* published by the Columbia University in the City of New York, Department of Graphics, School of Engineering and Applied Science, with the editorial co-operation of the Society of Photographic Scientists and Engineers. This Journal, which first appeared in March 1962, superseded the *Eastman Kodak Monthly Abstract Bulletin*, U.S.A., and *Ansco Abstracts*, U.S.A., both of which ceased publication in December 1961. The *Proceedings of the Centenary Conference* 1953 of the Royal Photographic Society include a report on other abstracting journals which cover photographic literature.

The first three of these abstracting journals deal with the more important patents in the field of photography. A full list of British patents will be found in *Abridgments of British Patent Specifications Group XX, Photography.*

The *World List of Scientific Periodicals* lists photographic journals published between 1900 and 1950, with the British libraries in which copies may be found. The British Museum has in preparation the *British Union Catalogue of Periodicals*, which will include many photographic journals.

Special scientific and technical books can in Britain be obtained on loan through one of the interlending library services. The National Central Library acts as an interlending centre for most public libraries and many specialist libraries, including that of the Royal Photographic Society and the research libraries of Ilford Ltd. and Kodak Ltd. The library of the London Science Museum, which itself has a collection of photographic books, acts as an interlending centre for scientific libraries. The Finsbury Central Library has the largest collection of books, pamphlets and periodicals on photography of any Public Library in the United Kingdom. This Metropolitan Special Collection is housed in St. Luke's Branch Library, Lever St., E.C.1.

A new international bibliographic guide to general and specialized literature on photographic processes, techniques, theory, chemistry, physics, apparatus, materials and applications, industry, history, biography, aesthetics, etc., entitled *Photographic Literature*, and edited by Albert Boni, was published in December 1962 by Morgan and Morgan, Inc., Publishers, New York.

N.W. (G.L.)

LITH FILM. Thinly coated emulsions which produce extremely sharp images of high density and contrast; used in the graphic arts for making line and screen images, and in some photo-typesetting systems. The characteristic curve of a lith film has a steeply rising straight-line portion, and a very short toe. When developed in a formaldehyde-hydroquinone developer, fully-exposed areas develop slowly at first, then, by a process of infectious development, rapidly increase in density.

Orthocromatic lith films are used for making black-and-white line and screen negatives and positives, in the camera or by contact. Half-tone images, made with either a cross-line or a contact screen, have well-formed dots which are suitable for reduction by dot etching. For normal images, the film is developed at 68° F. for a period of 2–3 minutes, but it may be developed by inspection when the growth of the image is checked by placing a safelight under a transparent dish, or by suspending one over and close to a white dish.

A special technique with lith films is fine-line development, used for copying screen proofs, type matter and thin lines. The developing dish is agitated for 20 seconds, then allowed to remain stationary for the remainder of the development period. Reaction products prevent the veiling over of fine detail. Another technique is the etch-bleach reversal process for making positives, where the gelatin and silver of a developed image area are dissolved, the unexposed silver halide is exposed to white light, and the film re-developed to form a positive image.

Lith films with a panchromatic sensitivity are used for making colour line and direct colour half-tone separation negatives.

F.G.W.

See also: *Developers; Graphic Arts; Photomechanical reproduction.*

LITHOGRAPHY. Method of mechanical printing from a flat surface where the printing areas accept greasy ink while the non-printing areas are dampened with water and repel the ink. The printing surface nowadays usually is a suitably grained zinc or aluminium plate, and the image is produced on it mostly by photographic means.

See also: *Photo-litho masters; Photomechanical reproduction.*

LITMUS. Vegetable colouring matter used as an indicator in chemistry; it is turned red by most acids and blue by alkalis. It is available

as a solid or a solution in water, or in rolls or books of litmus impregnated paper.

See also: *Indicator chemical.*

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

LITRE (LITER). The standard of capacity in the metric system. One litre is for all practical purposes equal to 1,000 cubic centimetres.

See also: *Weights and measures.*

LIVER OF SULPHUR. Chemical used in some toners; potassium sulphide. It is of variable composition.

LOCAL CONTROL. Any method of controlling the appearance of a limited area of the photographic image—e.g., to darken or lighten its tone. The term is applied to local control of development of the negative or positive, and dodging, shading and spot printing during exposure in making enlargements or contact prints.

LÖCHERER, ALOIS, 1815–62. German pharmaceutist, from 1847 professional portrait photographer in Munich. Noted for his photostory of the transport and setting up of the gigantic statue of Bavaria in 1850, and for Calotype portraits of celebrities published in 1854. Löcherer also made genre and nude studies for artists and reproductions of engravings in the Bavarian royal collection, 1855.

LOCKING CABLE RELEASE. A release which, by means of a locking screw or similar device, enables a shutter to be locked in the open position when it is set at "B".

LOGARITHM. Mathematical function used for making certain calculations easier. It is the "power" to which the "base" number (usually 10) has to be raised to equal a given number. For example, $100 = 10^2$, therefore the logarithm of 100 is 2·0. Its principal use in photography is to reduce the characteristic curve of the emulsion to a manageable form. The curve is required to show the effect of increasing exposure in a series of steps, each one representing a constant multiple of the value of the one before. The first step, for instance, may be from 1 to 10, while the last is from 10,000 to 100,000 exposure units.

If the curve were plotted normally, it would not be possible to give equal importance to the first and last steps (and in sensitometry they each have the same weight). The effect of using logarithms of the numbers instead of the numbers themselves is to give the same spacing along the exposure axis to every comparable step from the lowest to the highest values.

Some film speed systems use a logarithmic scale, where an increase of 10 degrees represents a ten-fold rise in speed. This means that a very great range of relative sensitivities can be accommodated on a comparatively short scale of numbers.

Logarithms to the base 2 are used in the formula for calculating exposure value numbers and also ASA log film speed degrees. Here every increase of 1 in the index number (exposure value or log speed) corresponds to a doubling of the basic value (exposure, speed).

LOGETRONIC. Proprietary name of first electronic printing and enlarging units utilizing a flying spot scanner.

LONG FOCUS. Description of a lens indicating that its focal length is longer than the diagonal of the negative it is designed to cover—i.e., longer than the focal length of a normal lens.

See also: *Lens; Telephoto lens.*

LONGMORE, T. A., 1905–57. English radiographer and medical photographer. Pioneered methods of training of workers in these fields and the standardized approach to clinical photography. Author of the first comprehensive text on these subjects (1944) which is now a standard work in worldwide use.

LONG SHOT. Large view in a cine film which takes in the entire scene or setting in which the action of a particular sequence takes place. It is generally a distant view—a landscape, street scene or the like out-of-doors, or the whole of a room in an indoor setting. Any human figures in a long shot would occupy less than one-third of the height of the frame.

LONG TOM. (Slang.) Abnormally high-powered telephoto lens of the type used by press photographers for taking sports pictures from a distance—e.g., at cricket matches and boat races. So called because of its resemblance to an old type of long-barrelled naval gun of that name.

LOW CONTRAST DEVELOPER. Certain developers tend to produce an image of lower contrast than others. They may be used deliberately to play down the over-harsh contrasts of certain subjects, or they may be employed because of other qualities associated with such developers—e.g., fine grain.

LOW KEY. Effect produced by a predominance of dark tones in a picture. Low key pictures have a heavy and dark character with a particular richness of shadow detail.

A low key photograph is a product of the right subject and suitable lighting; the effect cannot be successfully imitated with an unsuitable negative by any method of printing or aftertreatment.

The subject should be one which lends itself to dramatic, mysterious or rugged treatment and the actual tones should be inherently dark. A fair complexioned woman with blonde hair would be a bad choice for a low key study.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The lighting should limit the important parts of the subject to a narrow range of dark tones while at the same time providing good modelling. Unimportant areas and the background may be considerably darker than the subject, to give it emphasis. To relieve the over-all heaviness of tone there should be at least one small highlight area.

The exposure must be calculated specially for the tone range over the important part of the subject—not necessarily over the whole picture.

Under-exposure will result in loss of detail in the important tones; over-exposure will give better shadow rendering, but may burn out the highlights.

Development of the negative should be normal, but in a developer that favours good shadow detail—e.g., a metol sulphite developer. Under-development will cause loss of contrast, with murky and flat tones; over-development will increase contrast and destroy gradation in the smaller but quite important highlight areas.

The print should be made on a paper that is known to give good separation of the darker tones and which is capable of producing deep, rich blacks. Glossy and velours papers are excellent in this latter respect.

The only satisfactory way of arriving at the correct exposure is to make one or more test strips over the important areas, develop and fix them fully, and examine them by white light.

Without a lot of practice, it is almost impossible to select the correct strip under the darkroom safelight; the usual tendency is to err on the side of under-exposure.

When the print has been processed, care must be taken to preserve a clean, bright surface when it is dried. Hard water or insufficient washing can both lead to dulling of the surface sheen, which in turn causes a loss of contrast in the very dark tone areas. A final rinse in a weak solution of acetic acid usually prevents this trouble. J.D.C.

See also: *High key.*

LUMEN. Unit of light flux; it is the power of light falling on 1 square metre of a hollow sphere of 1 metre radius at the centre of which is a light source of 1 candle power. The total light flux emitted by the unit source is 4π lumens, 4π (= 12·57) being the area of the sphere of unit radius.

See also: *Light units.*

LUMEN SECOND. Unit used in measuring the total light output of a source—e.g., for stating the amount of light given out by a flash bulb, or the amount of light falling on a test piece of sensitized material. The quantity of light in lumen seconds is equal to the power of the source, expressed in lumens, multiplied by the duration in seconds.

See also: *Light units.*

LUMIÈRE, AUGUSTE, 1862–1954. French scientist, son of Antoine Lumière. With his brother, Louis, manufactured dry plates and later roll film. The two of them together did valuable work in photographic chemistry, colour photography and cinematography. Auguste was also famous in the sphere of biological science: founded the Clinique Auguste Lumière and devoted much of latter life to work in the physiological laboratory. Historically, his name is nearly always linked with his brother, Louis.

LUMIÈRE, LOUIS, 1864–1948. French scientist, son of Antoine Lumière who founded a dry-plate factory in Lyon in 1882. With his brother Auguste assisting, the factory expanded and started roll film manufacture in 1887.

Together with his brother, he carried out and published much scientific and technical work on photographic subjects. Louis and Auguste (alone and with Seyewetz) made valuable contributions to photographic chemistry, especially development (1891), and received the Progress Medal of the Royal Photographic Society in 1909. They produced Lippmann photographs in 1892, the Autochrome screen plate for colour photography in 1903 (commercially in 1906) and demonstrated publicly their Cinematographe camera and projector in 1895, using an intermittent (claw) movement with perforated 35 mm. film; the design followed in nearly all modern cine apparatus. In 1900 the two brothers demonstrated the Photorama, a 360° panoramic projection device. Biography by Bessy and Duca (Paris 1948).

LUMINANCE. Property of emitting light either as a source, or by reflection. The intrinsic luminance of a body (the amount of light coming from a unit area) is measured in foot lamberts—i.e., the intensity of the light falling on the surface measured in foot candles multiplied by the reflection factor of the surface.

See also: *Light units.*

LUMINESCENCE. Visible glow of certain substances when subjected to stimulation by electro-magnetic radiation, electric fields or heat. The general term luminescence also embraces phenomena like electro-luminescence, fluorescence and phosphorescence.

See also: *Electroluminescence; Fluorescent lamp.*

LUMINOUS FLUX. Intensity of light (i.e., visible radiation emitted by a source) or in common usage a measure of the power of the source. It is measured in lumens.

See also: *Light units.*

LUNAR CAUSTIC. Commercial form of silver nitrate, the chemical which enters into the composition of most of the sensitized materials used in photography.

LÜPPO-CRAMER, HINRICUS, 1871–1943. German scientist and writer on photography. A life-long worker in the photographic industry, first with Schering, then as manager of the Schleussner dry-plate factory, and later as technical director of the Kranseder dry-plate factory at Munich and as director of research in the Deutsche Gelatinefabrik A.G., Schweinfurt. He worked on hydroquinone-derivative developers (1902) and on desensitizers and in 1920 introduced his system of developing in bright light. Contributed notably to knowledge of colloid chemistry in relation to photography and to the latent image theory. The Royal Photographic Society granted him their Progress Medal in 1932.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LUX. Measure of the illumination over a surface.

A level of illumination of one lux means that one lumen of light is distributed over every square metre of surface. In other words, it is the illumination per square metre of a surface at a distance of 1 metre from a point source of 1 candela.

See also: *Light units.*

LUX SECOND. Unit based on the lux, used in sensitometry for measuring exposure.

It is the amount of light that falls in one second on a surface illuminated with an intensity of one lux.

See also: *Light units.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

M

MACH, ERNST, 1838–1916. Austrian physicist. The invention of X-ray stereoscopy is attributed to him. He suggested to Eder and Valenta that, by shifting the X-ray tube, it should be possible to produce stereoscopic radiographs. This was found to be correct and the first pictures so produced appeared in 1896. Mach was the first to use the electric spark as a light source in photographing projectiles 1885–6. He was also the first to use a rotating sector wheel in measuring sensitivity and was also a pioneer in stroboscopy and in time-lapse photography. Biography by A. Lampa (1918).

MACHINERY. Machines are photographed (a) to record their movements for analysis (b) to record their design or operating features for technical or catalogue illustration (c) for advertising purposes. As a preliminary to photography, a knowledge of the purpose of the machine and its method of operation, together with a clear understanding of its most important features, is necessary.

Motion Analysis. Movement is usually analyzed by "freezing" it by high speed photography, but sometimes the solution may involve integrating time, as in time-lapse photography.

The factors determining the method to be used and the equipment required are:

(1) the type of motion to be studied—intermittent, continuous or self-activated;

(2) speed of movement, often calculated or estimated from the frequency of movement and the distance travelled or based on design information;

(3) the amount of blur that can be tolerated in the photographic image (a relatively large degree of blur can often provide sufficient information);

(4) type of illumination—self-luminous or requiring front, side or rear lighting, diffuse or directional lighting, of continuous, intermittent or brief duration. On these factors depends the exposure necessary and hence the type of shutter, camera and form of lighting.

Some problems can be solved by using ordinary equipment. For others it is often necessary to use special apparatus, including:—magneto-optical shutters for exposure times of 2 to 20 microseconds; electro-optical Kerr cell shutters for times of 0·007 to 7 microseconds; electronic shutters (image converter tubes) for about 0·02 microseconds, or oconoscopes for about 2 microseconds. Illumination by electronic flash is suitable for exposures down to 1 microsecond, while sparks produced by capaciter discharges cover 1 to 0·1 microsecond. High-intensity continuous sources such as high-pressure mercury vapour lamps and xenon tubes may be needed for high-speed cinematography. Photo-cell, mechanical, electronic and acoustic triggering systems provide synchronization of the exposure with the event. Repetitive flash sources or shutter operation is used for stroboscopic recording. Other special equipment for high-speed work includes streak cameras, optical compensation (rotating drum and prism) cameras; image switching cameras and image sampling cameras.

Record Photography. This calls for the selection of emulsions and filters to show fine details and reveal differences of the surface textures and of the colours of the various materials and finishes that are used. Slow panchromatic emulsions are generally satisfactory but orthochromatic emulsions are often a better choice to show texture when the resultant reproduction of colour values is acceptable. An even spread of light is necessary for illuminating basic detail, but should be supplemented by directional lighting to create shadows that reveal shape and form and to produce reflected highlights to show up the nature and finish of the material. The most suitable form of lighting depends upon particular circumstances. At times the prevailing light for basic illumination, can be supplemented by a simple arrangement of lamps to fill-in dark areas and to create contrast. At other times existing light from unsuitable angles must be swamped by special illumination.

If the absence of movement and of extrane-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MACHINERY. When photographing inside a factory there are a number of points to watch, outside the picture area as well as in it. These include lamps that may cause flare, windows in the background (usually need covering up), vibration due to other machines (stop them if necessary), reflections from bright steel parts, and polished surfaces just outside the picture area.

ous light permits a sufficiently long exposure time, the area can be "painted" with light from a moving lamp to provide all required illumination. The direction of movement of the lamp needs preliminary testing to avoid unwanted glare from flat reflecting surfaces.

When long exposures are not possible due to vibrations, strong partial lighting, movement, etc., the light intensity must be increased. The problem then becomes mainly the physical one of installing lamps in sufficient quantity and in appropriate positions. The type of light source is less important.

Machinery with rotating parts in motion can often be photographed with long exposure times, the image blur giving a good impression of movement. Flash illumination can be used during such exposure to produce a superimposed sharper image of the moving part.

When figures are included in the picture, either because they cannot be removed or because they are required to give scale or to demonstrate a method of operation, pose them naturally and doing the right thing technically. Do not let them appear more important than the machine, and do not let them obscure any important part of the machine. Consult the safety officer to check that machine guards are correctly adjusted.

Look for objects that are out of place and for untidy details that may appear in the picture; have them removed from the scene.

Combine retouching to the obliteration of blemishes in the machinery and to the elimination of backgrounds by blocking-out. The latter task is much facilitated by paying attention to the background before exposing.

Backgrounds can be suppressed by controlling the illumination so that details are either underexposed or overexposed. Or get somebody to support a sheet behind the machine and to move it horizontally and vertically during the exposure to form a blurred image that isolates the machine from its surroundings. Select the camera angle so that the required details appear in the photograph clearly and without distortion and so that the required information is conveyed accurately.

Advertising. Any creative photography of machinery requires a different approach to produce a visual impact within the frame of the picture. This may mean selecting contrasting patterns and shapes and tonal areas, or bringing them out by suitable lighting. Unusual camera angles can emphasize perspective effects. When machine operators are included, choose the lighting and camera position to concentrate interest on either the operator or the machine. Generally the techniques required are pictorial rather than industrial—the impression rather than the technical information counts. R.F.

See also: *High-speed cinematography; High-speed photography; Industrial photography.*

MACKENZIE - WISHART ENVELOPE. Elaboration of the normal type of plate holder, enabling plates to be changed in daylight. Plates are loaded into light-tight envelopes which are then inserted in daylight into a special plate holder. The plate holder is so constructed that when the sheath is withdrawn, it opens the envelope and allows the plate to be exposed. Replacing the sheath closes the envelope again and allows it to be exchanged without a visit to the darkroom. With one of the special holders, the number of plates that can be changed and exposed is limited only by the number of loaded envelopes.

The envelopes are no longer made and are only to be had on the second-hand market.

MACKIE LINE. Clear line surrounding an intense highlight on a developed emulsion. It is the result of contamination of the solution by the waste products of development released in the highlight region. Only occurs when the developer is given insufficient agitation.

See also: *Eberhard effect; Edge effect; Kostinsky effect.*

MACPHERSON, ROBERT, 1811–72. Scottish surgeon in Edinburgh. Settled in Rome in early 1840s and became a painter. Changed to photography in 1851 and became the leading architectural photographer in Italy, particularly celebrated for his views of Rome and of sculpture in the Vatican. Devised a process of photolithography, 1855.

MACROPHOTOGRAPHY

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Technique of taking close-up photographs with ordinary camera lenses. Macrophotography ends and photomicrography (with microscope lenses) begins, at about 10× diameters.

Magnified pictures taken in this way are extremely useful for study and records in medicine, entomology, science and philately. They are also of striking general interest when of familiar small objects on an enlarged scale.

There are two ways of taking macrophotographs: by using a normal camera and lens with an abnormally long extension tube or bellows, and by using a large—e.g., whole plate, or 8 × 10 ins.—camera with an abnormally short focus lens. In either of these ways, an enlarged image of the subject is focused on the plate and photographed.

BASIC SYSTEM

The main consideration with a basic system is the type of equipment and lighting to use. Certain cameras and lenses are more suitable for macrophotography than others.

Focusing. The size of the camera for macrophotography is unimportant; anything from a miniature to a large plate camera will do. But it is essential for it to be equipped with a screen for visual focusing. It is possible to do ordinary close-up photography without focusing visually by measuring the lens-subject distance, or fixing it by a rod or other gauge. But in macro work, the lens is much closer to the subject than in ordinary close-ups. The depth of field is so shallow that the distance cannot be measured with sufficient accuracy; often a difference of 1/100 in. is enough to throw the subject right out of focus.

For subjects that are likely to move between focusing and exposure, a reflex camera or one with a reflex attachment is essential. If the subject is stationary, any plate camera or plate back attachment that will also take a focusing screen may be used.

CAMERA EXTENSION REQUIRED FOR MACROPHOTOGRAPHY

Focal Length of Lens		*Plate-Lens Separation*					
		Scale 1 : 1		*Scale 1 : 5*		*Scale 1 : 10*	
In.	*cm.*	*in.*	*cm.*	*in.*	*cm.*	*in.*	*cm.*
1	2·54	2	5·08	6	15·24	11	27·94
2	5·08	4	10·16	12	30·48	22	55·88
3	7·62	6	15·24	18	45·72	33	83·82
4	10·16	8	20·32	24	60·96	44	111·76
5	12·70	10	25·40	30	76·20	55	139·70
6	15·24	12	30·48	36	91·44	66	167·64

In the general case, for a lens of focal length = F and a magnification = M (times the size of the subject), the plate-lens separation S, measured from the back nodal point of the lens, is given by the equation:

$$S = F \times (M + 1)$$

The distance from the lens to the subject, measured from the front nodal point of the lens, is given by the equation:

$$D = F \times (1 + \frac{1}{M})$$

Advantages of Back Focusing. A camera with back focusing is a great advantage in macro work. This arrangement allows the lens to remain fixed in relation to the subject while the back is removed to focus the image. In this way the scale of magnification remains constant and focusing becomes more sensitive. When the image is focused by moving the lens only, comparatively large lens shifts may—especially near same-size reproduction—not lead to any plainly visible change of sharpness over a fairly wide range. The transition from sharp to unsharp becomes even more rapid at close range when the whole camera—with the lens and film fixed relative to each other—is moved nearer to or farther away from the subject. Such an abrupt change of sharpness is generally regarded as facilitating exact focusing.

Shutter. Instantaneous shutter speeds are not required in normal macro work; the brilliance of the image is so weakened by the amount of magnification that only time exposures are possible. All that is needed is a shutter that can be operated through a long flexible release without transmitting any vibration to the camera. Even this is not always necessary; the exposure may be made by switching the light on and off in an otherwise dark room. The exposure may also be made with a black card held in front of the lens after the dark slide has been drawn.

The situation is different when photographing moving specimens with electronic flash illumination. In this case the short duration of the flash is the thing that arrests the movement. As it lasts for less than 1/1000 second it can be synchronized to work with a fast shutter speed. By doing this, the shutter is not open long enough for the normal room illumination to form a secondary image. So for this particular technique it is an advantage to have a shutter synchronized for electronic flash at 1/100 second or less.

Lens. Most better quality lenses are perfectly suitable for macro-photography. Symmetrical lens designs are generally preferable. The main requirement for a macro-camera is adequate lens extension. Even for same-size reproduction the lens must be moved out to double its infinity distance from the image plane. This usually requires special close-up gear, such as extension tubes or extension bellows. They follow the general principles of such equipment for close-up photography, except that in macro work the over-all extension must be even greater to yield appreciable magnifications.

Normally camera lenses are computed for best definition at short image distances and

CC-0. Agamnan Digital Preservation Foundation, Chandigarh

long subject distances. In macro-photography these conditions are reversed, especially with unsymmetrical lens designs. At high magnifications it may be an advantage to use a normal camera lens reversed so that the rear component faces the object. This sometimes has the disadvantage that the diaphragm can only be adjusted from within the camera.

A standard lens also has the drawback that the large camera extension required for magnifications much above same-size may make it difficult to keep the whole camera set-up rigid. Any vibration is in addition magnified by the increased lens to film distance.

For this reason special short-focus macro lenses are available. For miniature cameras these may have focal lengths of 1 in. or less and are intended for specific magnification ranges. (A 1-in. lens, even with a normal covering angle of some 60°, will cover a 24 × 36 mm. negative area comfortably at same-size reproduction since the lens is then 2 ins. from the film. The same lens would not be able to cover that negative area when focused on infinity.)

Macro lenses need not have a large maximum aperture since the lens is usually stopped down appreciably to give a reasonable depth of field.

Depth of field in macro-photography depends, for a given standard of sharpness, only on the lens aperture and on the magnification. For a given scale of magnification it is therefore immaterial whether a short focus or a long focus lens is used. Where it is impossible to approach the object really closely, a lens of longer focal length has however the advantage that it gives the required scale of reproduction at a longer lens-to-object distance.

Stop Values. When a normal camera lens is used for macrophotography at abnormal plate-lens separations, the marked stop values no longer apply. The amount of light passing through the lens is the same irrespective of the camera extension, but at abnormal extensions it has to spread over a much bigger picture area. This means that for a given stop diameter, the bigger the picture, the weaker the image. And a weaker image needs a longer exposure.

The effective aperture, Ae, for a lens of focal length F with a rated aperture of Ar when working at an extension E, can be found from the equation:

$$Ae = \frac{E}{F} \times Ar$$

For example, if a 2 ins. lens stopped down to *f* 8 is being used to form an image magnified 5 × life size, the camera extension will be approximately 12 ins. So the effective aperture will be given by:

$$Ae = \frac{12}{2} \times \frac{8}{1} = 48$$

—i.e., *f* 48

The small *f*-value of a lens working at the magnification in macrophotography explains why the photographer must either use a very intense light source or be content to take pictures of still subjects which will allow him to give long exposures.

Of the two alternatives intense lighting is preferable, especially for colour photography. With very long exposures reciprocity failure may make it difficult to estimate the correct exposure time. For this reason flash lighting (see below) is ideal.

Camera Types. The two most suitable systems for macro-photography are on the one hand technical cameras with their double or triple bellows extensions, and on the other miniature and roll film reflex cameras with interchangeable lenses. A camera with a fixed lens, while usable for ordinary close-up photography with the aid of supplementary lenses, is not suitable for macro-photography. Here the power of supplementary lens that would be required to achieve magnifications above same-size reproduction usually leads to unacceptable deterioration of image quality.

For high magnifications with a technical camera a short focus lens is usually ideal. As already mentioned, this arrangement permits shorter camera extensions for a given magnification.

With miniature cameras the necessary lens-to-film separation can be achieved by extension tubes or extension bellows inserted between the lens unit and the camera body. If the camera is not itself a reflex model, a reflex housing, focusing stage or other focusing aid permitting visual focusing on a ground glass screen is required.

The same considerations apply to roll film reflexes (which also must take interchangeable lenses). In this case the scale of the set-up is necessarily also more bulky. Extension tubes and bellows for high magnifications are more readily available for 35 mm. miniature cameras.

Miniature cameras also have certain limitations. On the one hand the film capacity is an advantage where whole picture series are to be taken of the same subject or of similar subjects under identical conditions. But if conditions vary from frame to frame, it becomes more difficult to give uniformly correct exposures. Where only one or two photographs are to be taken, cutting off and processing short lengths of 35 mm. film tends to be cumbersome.

Normal Lighting. For still subjects almost any form of artificial light will provide satisfactory illumination; the power is unimportant since the exposure can be prolonged indefinitely. For preference, however, the light should be in the form of a beam of parallel rays of light rather than a flood of soft diffused rays. The appeal of macro pictures is in the normally invisible detail that they show, so that a fairly hard cross lighting is usually best.

An enlarger lamphouse with the negative carrier and lens removed makes an excellent

source of illumination, and equally good pictures can be made with a good focusing hand torch. The light from the torch is generally better for being slightly diffused through a sheet of ground or opal glass.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

When a hard light is shone across the specimen to emphasize detail, a second fill-in light or a white card reflector must be used to throw some illumination on to the shadow side of the subject. If this is not done, the parts in shadow will be completely black and featureless.

If an enlarger lamphouse is used it is often useful to fit a Photoflood in place of the normal lamp. The extra brilliance of the Photoflood compensates for the weak illumination of the enlarged image; it makes focusing easier and shortens the exposure. At the same time it generates a great deal of heat and must be used with caution, particularly on live insects or delicate plants.

Flash Bulb. Flash bulbs are a useful form of illumination for special subjects—e.g., for natural history photographs of living specimens in the field. The bulb can be brought close enough to the subject to make instantaneous exposures possible and as there are no weighty batteries involved, the set-up can be made easily portable.

It is often an advantage to use the flash bulb without a reflector when working close to the subject in this way. The reflector gives too broad a source of light when it is only a few inches away from the subject. This means that the shadows have no definite edges, and crisp detail is absent. Using the bulb alone reduces the width of the source and gives better rendering of detail and surface texture.

Flash bulb illumination is apt to be expensive for this type of work where a large number of exposures may have to be made to get a few acceptable pictures.

If the camera can be supported, open flash technique may be used at very small apertures, but with the popular type of midget flash bulb it is even possible to make synchronized exposures of 1/25 second and shorter on medium speed pan film at lens apertures of *f* 11 and smaller.

Electronic Flash. Electronic flash is perhaps the most suitable of all forms of illumination for macrophotography. It is bright enough to enable small apertures to be used, and its short duration arrests the movement of the liveliest insect. It is equally good even for still subjects because it cuts out any risk of camera shake during exposure. The cost per exposure is negligible, and the size of the source is small enough to give good definition at normal working distances.

A 100 joule flash will provide enough illumination to give fully exposed negatives magnified 10 × life size on medium speed pan film at apertures as small as *f* 36.

Ring Illuminator. A special type of electronic flash tube for very close working is manufactured in the form of a ring. The ring is big enough to encircle the lens of most cameras. A ring illuminator of this kind produces virtually no shadows since from the point of view of the lens looking through it, the light falling on the subject is uniform from all directions. For this reason the detail of the subject must consist of well-defined tone or colour differences or it will not show up at all. Any subject where the interest is mainly texture or detail in relief is better photographed with side-lighting. Ring illumination is useful in photographing cavities and it is the standard lighting for deep intra-oral dental photography.

Transmitted Light. Macro subjects are usually opaque, and so are normally illuminated from the front. But, particularly in laboratory work, it is often necessary to photograph specially prepared sections—e.g., of botanical or pathological specimens. Such sections—and other semi-transparent subjects like insects' wings—are best photographed by transmitted light. In this case there is no need for the exact methods of subject illumination that are necessary in photomicrography. Any of the light sources used for reflected light illumination may be used for transmitted light simply by directing them on to the back of the subject (which is held in position on a sheet of glass, or mounted like a microscope specimen).

A wide variety of effects can be obtained by changing the character and angle of the illumination. If the light shines directly from behind the subject, all the opaque parts will appear in silhouette and the result will be a strong black image without half tones. If the light shines obliquely on the subject the outlines of details will appear to glow against a dark background. (The appearance is similar to that produced by dark ground illumination in photomicrography.)

It is never a good arrangement to shine an undiffused light directly on to the back of the specimen as any uninterrupted rays fall on the lens and create flare and light fog. Where the details are to appear in silhouette, it is sufficient to place a sheet of white paper behind the subject and light it with a spot of light so that the subject is seen against a brilliant white ground.

With any system of transmitted light, there is a risk of halation and irradiation. These effects destroy the definition of fine detail, so they should be minimized by using backed plates and the minimum exposure.

SUBJECTS

The technique of macrophotography may vary according to the subject. There are two important divisions—still subjects and moving subjects.

Still Subjects. For still subjects there is no need for either reflex focusing or brilliant illumination.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The camera should be fixed firmly to the same table top or optical bench as the support for the subject to minimize the effect of vibration.

The set-up may be arranged vertically or horizontally. A horizontal arrangement is more suitable when a comparatively large and heavy plate camera body is used to provide the necessary bellows extension. A vertical arrangement is more suitable for a set-up consisting of say, a ¼-plate camera body and a long extension tube.

The light source, screened to prevent direct rays from falling on the lens, is mounted on an adjustable support so that it can be directed on to the subject from any angle.

In use, the subject is mounted in front of the lens and focused sharply on the screen with the lens at full aperture. The subject-lens distance is adjusted to give an image of the required size, and the lamp is moved about until the illumination is satisfactory. For most subjects the light should shine at an angle of about 45° from the front and to one side of the subject. A piece of white card is then held or fixed to reflect light on to the shadow side of the subject and adjusted until the shadow detail looks bright enough on the focusing screen.

The lens is then stopped down—generally to its smallest aperture—and the exposure made by covering and uncovering it with a piece of black card (after withdrawing the dark slide from the film holder if a technical camera is used).

Moving Subjects. For moving subjects, reflex focusing is essential. Some workers use an ordinary reflex camera, others prefer a miniature reflex or a miniature camera with a reflex attachment. The miniatures are handier for work in the field, but for extreme magnifications a miniature lens in a normal reflex camera is probably the best combination.

If the set-up is to be reasonably portable, the extension—and magnification—must be kept to the minimum. In this case the flash bulb or tube must be mounted on the camera; side lighting is out of the question. This means that some crispness of definition must be sacrificed.

A stationary arrangement can be constructed with a longer extension and this will handle greater magnifications. It also allows the flash to be placed to one side of the subject with a reflector to illuminate the shadows. This arrangement, whether vertical or horizontal, is suitable for photographing living insects, etc.

When an electronic flash tube is mounted on the camera in a portable set-up, the lens stop is dictated by the distance of the flash from the subject. With a stationary set-up, any stop may be used because the exposure can be regulated by moving the flash relative to the camera.

When working with flash it is generally necessary to employ an independent focusing light. This is because the magnified image is too feeble to be focused easily by the normal room or day light. A good electric torch, mounted on the side of the flash head and focused on the subject gives enough light.

In use, the focusing light is switched on and the lens opened out to full aperture while the subject is arranged and focused. When the image is satisfactory in position and sharpness, the lens is closed down to the working value and the release is pressed.

It is always a great help if the movement of the subject can be limited in some way so that once its image has been focused on the screen it cannot move either out of focus or off the plate. If this can be done, as soon as the image has been focused sharply, the lens can be stopped down to its working aperture and the subject observed directly. This enables the photographer to press the shutter release the moment the subject is in a favourable position instead of having to risk losing the picture at the critical instant. F.P.

MADDOX, RICHARD LEACH, 1816–1902. English doctor and amateur photographer. Inventor of the first workable silver bromide gelatin emulsion (1871). He made his ideas public "to point the way", without patenting this revolutionary process and passed his last years in straitened circumstances. Received the Progress Medal of the Royal Photographic Society in 1901 for his invention, which, with improvements by others, had laid the foundation of the dry plate and film industry.

MAGAZINE. Light-tight container for holding lengths of film or (in older versions) stacks of sheet film or plates. It is designed to be attached to or inserted in a still or cine camera, exposed, and then removed in normal light. A magazine therefore allows a camera to be operated continuously without the need for a darkroom for reloading, and it affords complete protection of the sensitized material before and after exposure. In many cases the film can be removed from the camera in the middle of its run with the loss of no or only a single exposure. Such a magazine incorporates a dark slide or similar device for rendering the film opening light-tight while the magazine is removed or interchanged against another.

35 mm. Magazines. Several 35 mm. cameras are designed for use with interchangeable magazines or magazine backs. These are almost invariably designed for a specific camera type and feature

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

INTERCHANGEABLE 35 mm. CAMERA BACK. This type of magazine locates the film accurately in the focal plane of the camera and permits changing in mid-film and reloading without rewinding. Safety interlocks to prevent fogging of film however make manipulation slightly involved.

INTERCHANGEABLE ROLL FILM MAGAZINES. The use of several pre-loaded magazines with a roll film camera designed for them permits a rapid interchange of film types as well as picture formats such as 2¼ × 2¼ inches, 1⅞ × 2¼ inches, etc., or a choice of roll film and 70 mm. film.

a film feed chamber, take-up chamber (with built-in spool), film track, and frame counting mechanism. A film indicator is usually also fitted. The magazine is loaded with 35 mm. film in standard cassettes, and on insertion in the camera engages the film transport mechanism of the latter. Interchanging magazines in the middle of the film is a simple operation, and the operative steps involve closing the film aperture with a dark slide or similar device.

In a 35 mm. camera the film plane must be correctly located within a small fraction of a mm., so this aspect calls for special precision in the design of the magazines as well as the camera. Two common systems are automatic film track location and mechanical camera location. In the first a pressure plate pushes the film forward into the film track of the camera itself when the magazine is loaded into the camera. This always positions the film correctly, but calls for fairly complicated design. Mechanical location systems rely on the magazine making contact with a specific and accurately machined part of the camera, locating studs or the frames of camera body and magazine respectively, usually serving this purpose. In this case the magazine has its own film track, and the precision of location is subject to wear and tear of the location surfaces, incidence of dust, grit, etc.

The magazines frequently incorporate safety interlocks to prevent accidental removal from the camera while the film aperture is open, accidental operation of the camera while the film aperture is closed, accidental opening of the magazine in daylight, etc.

Working with magazine backs permits rapid changing over from one film-type to another, and also makes possible rapid continuation of work at the end of a film, provided a second pre-loaded magazine is available. The use of magazine backs is sensible only if at least two such magazines are available.

Bulk Magazines. Magazine backs holding from 35 to 100 or more feet of film are available for certain 35 mm. cameras. These are intended for long shooting sequences where frequent reloading would be inconvenient (e.g. instrument recording, micro filming, etc.). Here the magazine is loaded directly from bulk film. It incorporates safety features similar to those of the normal interchangeable magazine-back, to prevent accidental fogging of the film.

In automatic recording cameras bulk magazines frequently are linked with automatic film transport devices.

Roll Film Magazines. These are available for specific roll film cameras (usually taking size 120 or perforated 70 mm. film) and also for press and technical cameras. In the latter case they are also known as roll film adaptors, and fit on to the camera back in place of the usual sheet film or plate holder. Roll film magazines for specific cameras again have to be designed individually for the camera. In principle they work in the same way as 35 mm. magazine backs, but usually have their own film track and are located by the fitting together of accurately machined surfaces on the camera and the magazine respectively. They are loaded with normal rolls of film (mostly size 120) or with cassettes of 70 mm. film.

Sheet Film Magazines. Magazines to hold six units of 4 × 5 ins. sheet film are made by one of the leading manufacturers of press-type cameras, to fit their own and similar press and technical cameras. All or any of the sheets may be removed for processing at any time without the remainder being wasted. Magazines holding different types of film can be interchanged easily and rapidly. Such magazines are particularly useful when it is necessary to keep exposed material in a particular order.

Cine Magazines. These are produced for cine cameras in gauges from 8 to 35 mm., and are available in various types. Standard magazines for certain 8, 9.5 and 16 mm. cameras are sold pre-loaded with film and are returned to the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

8 mm. CINE MAGAZINE. This takes spools of double-8 mm. film and is then easily inserted or changed round inside the cine camera, eliminating the need for elaborate loading manipulations.

maker for processing. The magazines may incorporate their own film transport movement to link up with the camera drive, or they may let the film run out of the magazine in a loop through a light-tight channel, for threading into the camera film track, where it engages with the film claw or other transport mechanism. With double 8 mm. cameras the use of a magazine speeds up the change over between the first and the second run of the film. With a few cameras the whole magazine turns over with part of the camera body, thus eliminating reloading.

Certain 8 mm. and 16 mm. magazines can be loaded by the user from standard 25 foot or larger spools. With 16 mm. and 9.5 mm. gauge the magazine itself can usually be removed from the camera in mid-film, with the loss of only a few frames. With double 8 mm. film this is not practical, since removal from the camera will fog also the film on the neighbouring track.

Professional 16 and 35 mm. cameras are mostly used in conjunction with robust magazines which are loaded from bulk supplies by the user and incorporate a footage indicator to show how much film remains unexposed in the magazine at any time.

L.A.M.

See also: *Cassette, Cine Camera.*

MAGAZINE CAMERA. Before the advent of roll film, many attempts were made to design a camera with a plate magazine incorporated so that it could take a number of exposures without the inconvenience of changing plate holders.

Some of these cameras held a dozen plates in a holder which kept the foremost plate pushed forward into the focal plane. After exposure, operation of a lever released the front plate and allowed it to fall into a storage chamber in the base of the camera. The next plate was then pushed into position automatically by a spring. These devices were temperamental and unpredictable in action and the attempts to improve them were abandoned on the arrival of the roll film.

A recent series of roll film cameras are designed to take magazines which are merely dropped into the camera, making it immediately ready for action. No spooling, rewinding, etc., are necessary, and the magazines are discarded on processing the film.

MAGAZINE PHOTOGRAPHY

The United States has exerted a strong influence on the styles and methods applied to magazine publishing in other countries. There is a world-wide tendency to follow the established patterns of American practice, on which this article is based.

Since the big picture magazines emphasize the picture story, it probably could be called the basis for magazine photography. It is the picture story which has been popularized most in latter years, and it is the picture story approach which holds the interest of most of the younger photographers.

Most general magazines which feature text also use pictures and many have one or more picture stories in every issue. The specialized, trade publication is also a major market.

Despite the growing, widespread interest in pictures for publication, the increasing number of photographers in the magazine field makes it a highly competitive one.

The Photographer. The average magazine photographer is a freelance. In the United States the majority are concentrated in New York City, with the second largest group deployed in and around Hollywood, but most major cities have one or more photographers who use them as bases for specializing in magazine photography in regions often consisting of several states.

Many magazine photographers have studios, with thousands of dollars worth of equipment. They usually specialize editorially in fashions or portraits or home suggestions, and may do most of their work for advertisers. Many others work with only a few small cameras but, since the advent of electronic flash, a travelling photographer may be so weighted down with paraphernalia that transportation becomes a serious problem.

To light up the whole arena when a circus appeared at Madison Square Garden in New York City, one photographer using colour employed 2,800 pounds of electronic flash equipment. A radio remote control set-up was also used, with a transmitter on his camera and a radio receiver activating the electronic flash. Flash bulbs are seldom used by the magazine photographer, whilst much of his work is still done in natural light.

Many magazine photographers spend most of their time travelling. In one ten-day period one freelance reported covering shots of hockey in New York one night, baseball near San Francisco the next morning, football at Los Angeles the next afternoon, another baseball game on the Mexican border the next day, a horse race at Santa Anita the next morning, another football match at Los Angeles the following day, and three ski stories at Sun Valley the next three days. Then, following a quick flight to New York and back to Los Angeles, he covered a travel story on the Pacific, en route to Hawaii.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The American freelance may be independent, or be represented by a picture agency. He usually works for a day rate, which may or may not be supplemented by a space rate, or for a story guarantee. Almost always, expenses are in addition to payment for his time. Although most photographers naturally prefer not to, some will work on speculation. They may or may not be members of the American Society of Magazine Photographers, which began as a professional society but changed its status to that of a union; it is seeking acceptance of a code which has as one of its central features a minimum daily rate of payment for magazine photographers.

The Pictures Wanted. Generalizations are difficult because magazines use all types of photographs, but a great deal of work—both black-and-white and colour—is done in 35 mm. and 120 size. In colour, the editors favour as large a transparency as the subject matter allows for best results, but not at the expense of editorial impact.

With its beginning in 1936, the pioneering American picture magazine, *Life*, presented this credo: "To see life, to see the world, to eye-witness great events, to watch the faces of the poor and the gestures of the proud, to see strange things, machines, armies, multitudes, shadows in the jungle and on the moon; to see man's work, his paintings, towers and discoveries; to see things dangerous to come to; the women that men love and many children; to see and to take pleasure in seeing; to see and be amazed; to see and be instructed; thus to see, and be shown, is now the will and new expectancy of half mankind."

Since then, television has whetted even more the desire of a visual-minded public to see as much as it can. And although the public is absorbed vitally in important events, it is just as interested when photography gives significance and meaning to the familiar, the commonplace, the ordinary. A magazine photographer can find dramatic, exciting, moving pictures in everyday life and day to day events.

Magazines of this type see pictures from all the major news services and are a focal point for submissions from the agencies and established photographers—but they are usually interested in contributions from anyone who thinks he has a printable picture, amateurs not excepted. In general they should be addressed to the Contributions Editor, but in the event of a major news break the nearest staff representative of the magazine could be contacted. If pictures which are submitted are trimmed, it is always a good idea to send a set of contact prints too.

Despite the general emphasis on the picture story, many magazines are also a market for outstanding single pictures. In Great Britain and other countries many of the leading illustrated magazines, have, in fact, ceased publication in recent years. There is today a greater demand for material suitable for specialized publications, rather than for the general features magazines, and also a greater market for single pictures and small features, instead of photo-stories.

Working Organization. The bulk of work for the leading American magazine is done by thirty-four staff photographers (thirty-two actually staff, two more on a contract basis for their exclusive services) and many freelances, some of whose work appears so regularly that they come to be identified with the magazine. Of the thirty-four, the biggest single group is located at the home office in New York. The others are distributed among the various domestic and foreign bureaux. Los Angeles and Chicago, for example, each have four staff photographers; Washington and Paris, three each.

Each staff photographer owns his basic equipment, but receives an annual amortization allowance. Many photographers own much in excess of their basic equipment, and the magazine also has a pool of equipment available to photographers working on assignment.

Some magazine photographers take their place among the great journalists of this day. In covering news, when the magazine is necessarily faced with following the newspapers, besides trying for better pictures, emphasis is placed on comprehensive, analytical, penetrative reportage. A picture taken from a fresh angle may be the difference. Frequently, effective layout is the answer.

Most photographers customarily work from a script presented by one of the magazine's special departments (e.g., religion, science, modern living, fashion, etc.) into which the editorial staff is divided. This script presents, as clearly and specifically as possible, the reason for the story, major angles to be developed and, when possible or necessary, definite picture ideas.

The script generally is merely advisory or suggestive. It gives the photographer a working basis for his story, but does not bind him to specific details (except in certain cases, such as a science or fashion story, where a particular point must be made in a particular way; and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

even in these instances the photographer may devise a better way).

All departmental scripts are presented to the picture department and the picture editor holds daily meetings with his assignment staff to consider them. When a script is approved, it becomes the function of the picture editor, with the help of his aides, to select the photographer.

Depending upon the time and scene of the story, the picture editor makes every effort to choose, from among his available staff and freelance photographers, the right man or woman for the story being considered. Some photographers complain that, as a result, there is too much "typing" of photographers. This complaint certainly has some basis but does not take into account one prominent photographer's comparison of photography to spaghetti: "It all depends on the sauce." In this case, the "sauce" is the photographer's style.

Many magazine photographers consider themselves artists—and a few are. Better reproduction facilities permit a magazine to regard a photographer's mental and emotional approach as much more important than the mechanical. A certain technical competency is assumed, but a technically poor picture which tells a story is preferable to a better quality picture which does not.

Editorial Routine. A magazine photographer is generally accompanied on an assignment by a reporter, i.e., a researcher, a junior editorial worker who helps with arrangements and writes captions. Frequently the photographer never sees the pictures he takes until they are published. The film is sent by express delivery to the darkroom, where it is processed and delivered to the negative readers who edit the contact prints into story form; this is done with the help of the photographer and/or researcher, if either can be present, or from captions. Although most of the bureaux have their own processing facilities, the average story—in the interest of speed in handling—is sent to the central office, which returns a set of contact prints to the photographer.

The photographer may have taken hundreds even thousands of pictures, of which only relatively a few have any chance of being used, even when the story is successful. This over-shooting has a purpose: greater slectivity.

In the form it is presented to the editors for consideration and possible layout, the picture story is printed full scale on glossy, single-weight paper in sizes of 8 × 10 ins. or 11 × 14 ins. for the more outstanding pictures.

A picture story ranges from a page and a half to the "photographic essay", a major presentation, of usually seven to nine pages, either in black-and-white or colour, often with the photographer's credit line. In making photographs the photographer should supply some pictures of vertical, and some of horizontal, format. Each feature should have a key picture —one picture which pinpoints the essence of the whole story.

Normally, the magazine's last black-and-white pages close four days before publication. A black-and-white cover would have been selected a week before and the first pages of an issue usually close nine days before publication.

The bulk of the colour pages are scheduled about nine weeks in advance, but up to six pages an issue may be allotted to "fast colour", with a normal sixteen-day closing. This development offers the opportunity of presenting stories, as well as single pictures in colour on a quick schedule.

MAGENTA. Secondary colour, of a purplish-red shade, complementary to green. Sometimes also called minus-green—i.e., white with the green component removed leaving only blue and red. Magenta dyes are used in subtractive colour synthesis to colour the image formed in the green-sensitive layer of an integral tripack colour film.

MAGENTA CONTACT SCREEN. A contact screen composed of magenta dyed dots of variable density, used for making half-tone negatives in the camera.

See also: *Half-tone screen.*

MAGIC LANTERN. Early name for a slide projector. The term is still sometimes used by non-photographers.

See also: *Projector (still).*

MAGIC PICTURES. One-time popular photographic novelty. It consisted of a sheet of apparently plain paper on which an image was made to appear by warming the paper or breathing on it.

One method of making such pictures was to bleach out a fixed, but not toned, albumen paper print. By pressing this into contact with a piece of cloth or blotting paper damped with hypo solution, the image could be made to reappear.

See also: *Printing processes (obsolete).*

MAGILP. Mixture of linseed oil and mastic varnish, originally an oil-painter's medium, but also used as a thinner in the oil and bromoil processes and for imparting a gloss to matt or textured surface bromide prints. Also known as megilp.

See also: *Doping prints.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MAGNESIUM. Used as ribbon or wire to provide a cheap and convenient source of light for still photography and contact printing. The ribbon, 100 cm. of which weighs about 1 gram, can be lighted with a match. It burns with an intensely actinic light—and, unfortunately, a considerable amount of white smoke.

As it oxidizes rapidly, the ribbon is stored in an air-tight box, just as much as required being pulled through a slit.

The light from a given length is reasonably constant, so that an exposure can be repeated exactly by burning the same length of ribbon at the same distance.

The exposure required for magnesium ribbon depends upon the weight of magnesium burned. 1 gram of ribbon (about 5 ins. of ribbon 1/12 in. wide) gives a light with a guide number of approximately 30 when used with a medium speed pan film. The approximate length of magnesium to give a fully exposed picture of a subject in a room with light walls and ceiling is shown in the table below.

Where the length is too great to be handled easily, the ribbon can be roughly woven into a square mat and lighted at one corner.

EXPOSURES FOR MAGNESIUM RIBBON

Distance	Inches of Magnesium Ribbon Required at Aperture f 8		
Feet	Film Speed Slow	Film Speed Medium	Film Speed Fast
5	10	5	2½
10	30	15	7½
13	45	22½	11½

At one time, magnesium was also very commonly used in powder form as a constituent of flash powder. A typical formula is as follows: magnesium powder, 6 parts; potassium chlorate, 4 parts; manganese dioxide, 1 part.

Flash photograph is now nearly always done with flash bulbs or electronic flash.

See also: *Flash powder; Light sources.*

MAGNET FILM. Narrow gauge or full width (35 mm.) cine film with standard perforations, fully coated with a magnetic oxide layer instead of a photographic emulsion. Also known as magnetic film. Used for live sound recording in professional motion picture practice. The perforation of the film ensures exact and consistent synchronization of the sound with the picture.

The sound recording from the magnetic film may be transcribed (after appropriate editing of picture and sound) on to an optical sound track to be combined with the image on the final release prints.

Alternatively a magnet-film with the final sound track may be run through the reproducing equipment in synchronism with the film being projected.

See also: *Sound recording; Sound synchronization.*

MAGNETIC STRIPE. Narrow strip of a magnetic iron oxide layer applied near the edge along narrow gauge cine films. The stripe serves for recording and playing back a sound track accompanying the film. It is applied in various ways, either during the manufacture of the film (immediately after coating the emulsion) or after processing.

See also: *Sound recording; Sound synchronization.*

MAGNETIC TAPE. Sound recording medium in magnetic tape recorders. It consists of a flexible base of cellulose acetate, PVC or polyester, ¼ in. wide and 0·002 in. or less thick, coated with magnetic iron oxide—normally on one side only. The tape is supplied wound on to plastic reels in standard sizes and lengths.

The playing (or recording) time of a spool of tape on a particular machine depends on the recording speed of the machine, the number of tracks recorded over the width of the tape and the thickness of the tape (since the thinner the tape the more can be wound on a spool of a given size).

Tape is manufactured in four different thicknesses, known from their relative playing times per spool as Standard, Long Play, Double Play and Treble Play. The thicker tapes are more robust, less troubled by "print through" (transference of the record between layers on the spool), and cheaper for a given length than the thinner tapes. However, the thinner tapes allow more material to be recorded on a given spool size. For example a 7 in. spool can hold up to 3,6000 feet of treble play tape—giving a total playing time of 6 hours at 3¾ ins. per second on a twin-track recorder. Being more flexible, thin tapes can be held in closer contact with the face of the recording head. On quarter track recorders where the actual width of the recording is less than 1/16 in., poor contact between tape and head seriously affects the reproduction quality. For this reason, Standard tape is never used on quarter track recorders where quality is important, and in any case this tape is virtually obsolete.

Perforated Tape. Some tape attachments for coupling a tape recorder to a cine projector employ perforated tape to ensure accurate synchronization between sound track and picture. This tape is perforated to run over the standard 8 mm. cine film sprockets. The perforations occupy half the effective width of the tape so the sound track may consist of a single half track recording or two quarter track recordings.

Magnetic Film. For sound recording in motion picture studios a 16 mm. or 35 mm. perforated film is sometimes used, carrying a magnetic oxide coating in place of the photographic emulsion. This has the advantages of perforated tape, and also permits recording with a wider track or with several tracks on the same film. The film is edited together with the picture film

CC-0. Anand Digital Preservation Foundation, Chandigarh

and then serves for the production of a release print of a motion picture with an optical sound track.

Striped Cine Film. The functions of recording tape and cine film can be combined by coating the magnetic iron oxide on to the edge of the photographic film. The coating is applied in various ways—e.g. as a full stripe (0·1 in. wide) on the unperforated edge of single perforated film or as a half stripe (0·03 in. wide) on both sides of single perforated film. A balancing stripe is in most cases applied to the opposite edge of the film to the one carrying the record to enable the film to be spooled up evenly. Film of this type is used principally for the production of the final married print of a sound and picture squence separately recorded.

Video Tape. This is a special type of magnetic tape used for recording the television picture signal. Because of the greater amount of information to be carry, video tape must be wider and run at a higher speed than normal sound recording tape. A typical 2 ins. wide tape runs through the video tape recorder at 6–12 ins. per second. The signal is, however, recorded across the tape by a fast rotating set of recording heads. The effective head-to-tape speed may be as high as 1,500 ins. per second for broadcast standards, or as low as 200 ins. per second for closed-circuit TV requirements. Where the information to be stored is simpler, or a lower standard of picture quality is acceptable, a narrower tape may be employed—e.g. 1 in. wide. Even ¼ in. tape with a linear speed of 120 ins. per second has been used for video recording.

MAGNIFICATION

Relationship, usually represented by the letter M, between the size of the object photographed and the image of it formed by the lens. The sizes of the object and image are proportional to their distances from the nearer nodal points of the lens. If the image distance is v, and the object distance u, then

$$M = \frac{v}{u}.$$

Basic Equations. In normal photography where the object distance u is large compared with the image distance v, the image is very much smaller than the object and M is a fraction. For this reason the relationship between the two is often expressed as a reduction, r, which is the reciprocal of magnification—i.e.,

$$r = \frac{1}{M}.$$

On the other hand, it is equally common practice to regard M as expressing the ratio of the image and object sizes without any implication of actual increase in size—i.e., when M is less than unity, the image is reduced; when it is larger than unity, the image is enlarged.

The magnification can also be expressed in terms of the focal length, *f*, of the lens:

Taking the fundamental equation for an object distance u and image distance v,

$$\frac{1}{F} = \frac{1}{u} + \frac{1}{v}$$

and multiplying both sides by v, then

$$\frac{v}{F} = v\left(\frac{1}{u} + \frac{1}{v}\right) = \frac{v}{u} + 1$$

or

$$v = F\left(\frac{v}{u} + 1\right)$$

and since

$$M = \frac{v}{u} \text{ (above)}$$

then

$$(1)\ v = F(M + 1)$$

and

$$(2)\ u = \frac{F}{M}(M + 1) = F\left(1 + \frac{1}{M}\right)$$

These formulae for v and u are the fundamental formulae of magnification and they also

ENLARGER MAGNIFICATION. The relative positions of negative and paper depend on the focal length of the lens and the magnification employed. With a given separation of negative and enlargement there are two lens positions at which a sharp image is formed; in one case an enlarged image, and in the other a reduced one (dotted lens). The factors are: f, focal length; M, magnification; N_1 and N_2, nodal points.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

represent the relative separations that will produce a magnification = M. From them it is possible to calculate every image and object size and the separation relationships encountered in photography. Some typical examples are worked out below.

(1) What is the maximum scale of reproduction that can be obtained with a 6 ins. lens and a camera extension of 9 ins.?

$$(v = 9, F = 6)$$

from equation (1)

$$9 = 6\,(M + 1)$$

therefore

$$M = \frac{9}{6} - 1 = \frac{1}{2}$$

In other words, using the full extension, the negative image will be half the length or width of the object.

(2) An enlarger has a maximum negative-lens separation of 5 ins. What is the smallest image it will give with a 3 ins. lens?

(u = 5—since the negative is the "object" — F = 3)

From the equation we get:

$$u = F\left(1 + \frac{1}{M}\right)$$

$$5 = 3\left(1 + \frac{1}{M}\right)$$

$$\frac{1}{M} = \frac{5}{3} - 1 = \frac{2}{3}$$

therefore M = 1·5.

In other words, the image on the enlarger easel will be one and a half times as long or as wide as the negative.

(3) A 5 cm. lens is to be used for macro-photography up to a magnification of 10 ×. What total lens-film separation (v) must be allowed for?

$$(F = 5, M = 10)$$

from equation (1)

$$v = 5\,(10 + 1) = 55 \text{ cm.}$$

This (less the maximum extended length of the camera) would be the length of the extension tube required to give an image enlarged 10× with the lens in question.

In practice, the image and object distances in all the above examples must be measured from the nearest nodal point of the lens, and the distance separating the nodal points must be added to the over-all length of the resulting set-up.

If the expressions for object and image distances are added, the result will be the total separation of the object and image planes (neglecting the relatively small separation of the nodal points)—i.e.,

$$v + u = F(M + 1) + F\left(1 + \frac{1}{M}\right)$$

$$= F\left(M + 1 + 1 + \frac{1}{M}\right)$$

$$= F\left(M + \frac{1}{M} + 2\right)$$

For any given total distance of v + u, there are two values of M that will satisfy the equation. This simply means that there are two possible positions of the lens which will give a sharp image; one which gives a magnified image, and the other reduced image. The only exception is where the lens is midway between the planes and M = 1; in other words, when the object and image sizes and the corresponding separations are equal.

Exposure Factor. The light passing power of a lens depends both on the actual lens diameter and on the distance from the lens opening to the image plane (i.e. the film). In normal photography of distant to reasonably close subjects the lens-to-film distance does not vary a great deal, and for exposure purposes we can assume this to be approximately equal to the focal length of the lens. It thus becomes possible to specify the light-passing power of the lens opening in terms of the *f*-number—i.e., the ratio of the focal length to the optical lens diameter. This is convenient because it provides a way of calibrating the lens openings of any lens in terms of their exposure effect.

With very near subjects, photographed at magnifications of 0·1 and larger, this approximation is no longer accurate enough. The exposure must then be increased by a factor which is the square of the actual lens-to-film distance divided by the square of the focal length of the lens.

MAGNIFICATION AND IMAGE SIZE. 1. Image distance much smaller than the object distance; image greatly reduced. 2. A long focus lens increases the image distance and thus yields a larger image. 3. Reducing object distance and increasing image distance also increases scale of reproduction. In all cases: u, object distance; v, image distance.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In practice this exposure factor can also be expressed in terms of the magnification, which yields a very simple equation:

$$\text{Exposure factor} = (M + 1)^2$$

Thus for a close-up in half natural size ($M = 0{\cdot}5$) we get an exposure factor of $(0{\cdot}5 + 1)^2 = 2\frac{1}{4}$. For full size reproduction the exposure factor becomes $(1 + 1)^2$, or 4 X. At high magnifications it increases very rapidly.

This exposure factor applies only where the lens is extended beyond the infinity position for close focusing. With supplementary lenses the effective lens-to-film distance remains almost unchanged and no exposure increase is necessary.

Magnifying Devices. The magnification of the image is decided by the ratio of the object and image distances, so any device that either shortens the object distance or lengthens the image distance, will increase the magnification.

(1) The distance of the object from the lens can be shortened easily by bringing the lens closer to the subject. When this is done, to maintain sharp focus, the distance between the lens and the image plane must be correspondingly increased—e.g., by camera extension or by adding extension tubes. If the lens has a relatively long focal length, this increase will be considerable. To reduce the extension to practical proportions at large magnifications the focal length of the lens must be kept as short as possible, either by fitting another lens, or by adding a supplementary lens to the camera lens.

For macrophotography up to a magnification of about 10×, 5 cm. is the longest practicable length. In dealing with microscopic objects the lens may have a focal length as short as 1/12 in. and work almost in contact with the subject.

(2) Where it is not practicable to bring the lens close to the subject, the magnification can be increased by increasing the lens-image separation—i.e., by using a lens of longer focal length or (up to moderate amounts) by adding a negative supplementary lens. In this case magnification is a relative term; the image is generally much smaller than the object, but larger than with the normal camera lens.

The telephoto lens is a special case because it gives a magnified image without requiring any increase in camera extension over a normal lens. The explanation is simply that the construction of the telephoto lens brings the rear nodal point in front of the lens. As the image-lens separation is measured to the rear nodal point, the effective distance is much greater than the physical separation or the separation given by a normal lens.

The magnifying effect of a telephoto lens is not quoted in terms of the ratio of image to object size; it is expressed as the power of the lens, a figure (written 2×, 3× and so on) that indicates how many times in linear measurement the telephoto image is bigger than the image of a normal lens with the same back focus.

MAKE-UP FOR PHOTOGRAPHY

Make-up serves the photographer in two ways: it eliminates the need for most or all of the retouching on the negative and print, and it adds to the attraction of the model. Make-up will obliterate patchy skin tones, blemishes and lines, and it can also change the shape of the whole face or of individual features.

Corrective Make-Up. Corrective make-up is make-up applied to change the proportions of the face—e.g., to narrow a too-broad nose or

MAKE-UP FOR BLACK-AND-WHITE PHOTOGRAPHS (ON PANCHROMATIC MATERIAL)

	WOMEN	*MEN*
Pan-stik or Pan-cake make-up	6N	9N
Powder	Translucent	Tech. Special
Eyeshadow (Lining colour)	6 (Blue-grey) or 22 (brown)	22 (Brown)
Pencil	Light Brown, brown brownish-black, black	Brown, brownish-black
Lipstick	Sparkling scarlet	
Moist rouge (lips)		
Mascara	Brownish-black, black	T-3
Dry rouge	Light Tech.	Optional Dark Tech.

Women with dark or tanned complexion, use 7N Pan-stik or Pan-cake. Men with dark or tanned complexion use 10N Pan-stik or Pan-cake.

To highlight areas of face, use Pan-stik or Pan-cake several shades lighter than foundation colour: 3N for women; 6N for men.

To shadow areas of face, use Pan-stik or Pan-cake several shades darker than foundation colour: 9N for women; Light Egyptian for men.

Erace may also be used to lighten shadows under eyes.

Women may also use blue, green, or blue-green eyeshadow sticks as well as 6 or 22 lining colour. Available with or without iridescence.

Lighter shade than Sparkling Scarlet lipstick is Clear Clear Red; darker shade is Brilliant Red.

Mascara is available in Cake, Cream or Wand.

Dry rouge is used to give more natural appearance to completed make-up.

Pan-cake may also be used as body make-up.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MAKE-UP CHART. A, *foundation; determines the general tint of the complexion. This is also applied to all visible body portions (e.g., neck, shoulders, etc.).* B, *eyelash make-up; usually black for dark complexions, left untouched for light faces.* C, *pencil for eyebrows and eyes.* D, *eye shadow.* E, *highlights (under eyes, also around mouth and nose; generally applied with a wet brush, and blended into the foundation with a dry brush).* F, *shading; often applied initially underneath foundation, the latter then being rubbed away to bring up the shadows.* G, *lip-stick or lip paint; may be applied with a brush.*

jaw, or to remove a double chin. This is done by applying suitable highlights and shadows with make-up of the right colour. It is important to use make-up colours that look right to the sensitive material in the camera.

Colours that merely look right to the eye may reproduce in a completely different tone in the photograph.

It has become common practice for normal portraiture to use panchromatic films or plates in conjunction with the range of make-up colours specially produced for the purpose, such as Max Factor Panchromatic Make-up. The brightness of each shade of make-up colour is indicated by a number.

A highlight is normally made three or four shades lighter than the foundation colour, and a shadow, three or four shades darker. For example, if the foundation colour or basic skin tone has been applied in 6N Pan-Cake, then 2N or 3N would be used for the highlight and 9N or 10N for the shadow.

Application of the Make-Up. The face to be made up must be clean, dry, and free from any grease or oil. The shadow areas are first filled in with Pan-Cake shadows; using a sponge for

MAKE-UP CHART FOR COLOUR PHOTOGRAPHY (EASTMAN FILM 5251 (35 mm.) and EKTACHROME 7255 (16 mm.))

	WOMEN	*MEN*
Pan-stik	7-25B; 7-25BC; 7-25CN	7-25EN; 7-25FN; 7-25GN
Powder	Translucent	Tech. special
Creme rouge	Flame	None
Dry rouge	Flame or Light Tech.	Dark Tech.
Moist rouge (Lips)		T-3, T-2 (Dark)
Lipstick	7-22; 7-22B	
Eyeshadow (Lining colour)	7-34 (Grey-brown) No. 3 (brown)	No. 3 Brown
Eyeshadow Stik	1R. Brown, 1R. Grey	
Fluid Eyeliner	Brown, brownish-black; black	
Eyebrow pencil	Light Brown, brown, brownish-black	Brown, brownish-black
Mascara	Brown, brownish-black or black	Optional

Apply Pan-stik foundation and blend very thin.

Eyeshadow colours other than grey or brown may be used for more dramatic eye effect.

Pan-cake shades, if preferred to Pan-stik, are 7-25A, B, C, D, E, F, G, H. Pan-cake may also be used as body make-up if necessary.

For Kodacolor (stills) and for Ektacolor (stills) use Society shades of make-up. Select Pan-stik or Pan-cake foundation one shade darker than natural skin tone. Lipstick shades in medium pink, clear red or orange tones photograph best. Dark blue-reds are to be avoided.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

APPLYING MAKE-UP. 1. Apply basic shadows with make-up cake (except eye shadow). Use brush for small areas, sponge for large ones. 2. Cover whole face with foundation cream. 3. Apply highlights (under eyes, lines around mouth or nose) with wet brush, and blend into foundation with clean dry brush. 4. Moisten eyelids with cream and apply eye shadow with finger tips. 5. Powder over make-up with powder puff. 6. Line eyebrows with eyebrow pencil and apply eye-lash make-up. Also make up lips using a suitable thin brush. 7. Rub shadow areas with finger tips (as applied in the beginning) to make them show up through the foundation. 8. Apply cheek rouge with a brush and blend carefully into face tone.

large ones, and a brush for small. The sponge or brush is wetted, rubbed on the cake of make-up, and applied to the area to be shadowed. If the jaws are to be shadowed, they are dealt with first.

Then nose shadows, if needed, are applied with a flat blending brush.

If the make-up is used in stick form—e.g., Max Factor Pan-Stik—the foundation colour is put on first, stroked on straight from the container and blended with fingertips or damp sponge to a smooth even texture. Highlights and shadows are applied afterwards with blending brushes or the finger tips.

Once the shadows are all filled in, the whole face is covered with the Pan-Cake foundation colour, completely concealing the shadows previously applied.

Pan-Cake highlights are next applied with a wet brush under the eyes and in the lines around the mouth and nose. The highlights are then blended into the foundation with a clean, dry brush.

Eye shadow is next applied, the eyelids being first moistened with a little cream so that the eye shadow will blend to an even tone with the Pan-Cake base.

When the make-up is completely dry, it is lightly powdered and buffed all over with a powder puff to produce a smooth skin texture and remove excess Pan-Cake which dries as surplus residue.

The whole face is now brushed with a powder brush.

To complete the make-up, the eyes are lined with pencil, eyebrows are made-up, eye-lash make-up is applied, and finally, lipstick.

At this point the shadow areas are lightly rubbed with the finger tips. This makes the shadows appear according to the amount of rubbing, giving complete control of the final effect. Normally the shadows are rubbed until they are only just visible, in which state they will appear completely natural in the photograph. The effect is best judged by looking into a mirror at arm's length. If the shadow is just barely visible, it will photograph well.

The general effect is enhanced by brushing dry rouge sparingly on to the cheeks: a light shade (Max Factor Light Tech.) for women, and a darker shade (Max Factor Dark Tech.) for men.

This improves the modelling of the cheek-bones and adds sparkle to the eyes.

Make-up that has been on for some time and lost its freshness may be restored by powdering over with a powder two or three shades lighter than the one originally used.

A model with a dry skin can prevent cake make-up from looking dry and flaky by using Invisible foundation cream before making up the face.

Photographic Make-up Kit. The following list gives the composition of a suitable kit for photographic make-up.

3 Pan-Cake, Pan-Stik or S.S. Grease (one for base, one for highlighting and one for shadowing).

1 White Lining (No. 12)
1 No. 6 Lining (dark grey)
1 No. 25 Face Powder
1 Moist Rouge (No. 2 Special)
1 Eyebrow Pencil
1 Eyelash Make-up
1 Cleansing Lotion or Cream
1 Skin Freshener
1 Powder Puff or Powder Brush
1 Lip Brush
1 Sponge

If colour film is to be televised in black-and-white, use a minimum of cheek rouge. The foundation colour chosen may be a shade darker than the normal skin tone. M.F.

Books: *Photographic Make-up*, by J. Emerald; *The Technique of Film and Television Make-up*, by V. J. R. Kehoe (both London).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MANLY, THOMAS, 18??–1932. English photographer. Improved in 1898 the Marion transfer process for gum-bichromate pigment prints and patented it under the name Ozotype. In 1905 he described his Ozobrome process in which a gelatin silver bromide image is transferred by contact to a pigment paper. From this H. F. Farmer worked out the carbro process (1919) which was put on the market by the Autotype Company.

MANUSCRIPTS AND OLD DOCUMENTS

Normal document copying is carried out with special permanent equipment. But the photographer who is interested in copying old and rare documents in museums, libraries, churches, and private collections, almost always has to go to his subject and photograph it under unfavourable conditions with the equipment that he takes along with him. This is a special field of photography, and even of document photography.

Typical subjects include old photographs, maps, plans, drawings, etchings, printed books, and manuscripts, each presenting a different problem, and needing to be treated in a different way. Usually the photographs are required for illustrated articles or books on the subject they depict, as examples of a period in art or history, or for study and records. These subjects are usually found in public or private collections—and anyone privileged to photograph them should treat these old collections with the greatest of care, first because they are usually unique and for that reason above price, and secondly in fairness to other photographers.

Equipment. Sharpness and detail are most essential for this type of photograph. And while there is much to be said for the miniature camera, a 8 × 10 ins. or whole-plate camera is the most suitable for this sort of work—preferably of the square-bellows, back-rack-and-pinion focusing type. If miniature equipment is used it should be in the form of the single-lens reflex, which allows the use of interchangeable lenses, and of extension tubes or bellows.

For good definition, an anastigmatic lens of *f*7·7 at full aperture is all that is required as the subject is still and can be given a long exposure.

The most convenient focal length depends on the scale to be copied. Often a same-size picture is required; sometimes an even larger scale is wanted.

The following table indicates the camera extension necessary for various scales of reproduction:

SCALE AND CAMERA EXTENSION

Lens-to-Film Distance		*Scale of Image*
¼ more than focal length	=	¼ object size
½ more than focal length	=	½ object size
double focal length	=	same size
3 times focal length	=	twice scale
4 times focal length	=	3 times scale

Filters are essential for copying coloured, tinted, or faded originals. A 2× yellow and if possible a tricolour set of four should be included in the equipment, preferably of gelatin sealed between optical flats. The filters are best held behind the lens in a three-sided frame screwed or clipped to the lens panel. Final focusing should always be done with the filter in position, to avoid errors due to possible lens aberrations.

Because of the need for accurate focusing, a magnifier is most necessary—either one of the proprietary instruments or one of the linen tester type which does a good job of work and has the advantage of being pocket size.

An ordinary tripod should be avoided if possible because the camera must be dead square with the original, and even when the tripod has rubber feet it is an awkward thing to set accurately on a polished floor. The most useful thing is the centre pillar type of stand. This means extra weight to carry around, but the legs are completely adjustable for uneven surfaces and the head can be set to the exact height required with the turn of the handle. The tilting top also gives any angle required—even vertical—which means that the subject can be laid flat on the floor and photographed from above.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

HOLDING OLD DOCUMENTS. Two lengths of tape (at top and bottom) are pinned to an easel and long pins stuck through the tape to press flat against the document. This holds the document securely in position without any risk of damage—an important point with old manuscripts.

Odd items of equipment that are useful for this work include: drawing pins, household pins (including very large ones if possible), strong tape about ¾ in. wide (bookbinder's tape is ideal if obtainable), a pair of clamps and at least four large bulldog clips with strips of chamois leather stuck over the jaws to prevent damage and grip more firmly; a couple of wooden wedges, about four inches long, one inch wide, and about one inch at the thick end, are useful for levelling; a length of good stout string and a pocket tape measure for checking distances. At some time all these items will be needed in setting up the various subjects dealt with. Improvisation is a valuable art.

The photographs may be taken on plates or film. The normal subject will usually be covered by a slow panchromatic or orthochromatic material, but sometimes a process or pan-process is better. This does not mean that all these types have to be carried around. It is nearly always possible to find out in advance which will be needed.

Setting Up. This is the operation that calls for improvisation. A given subject may be unmounted and it may not be permissible to stick pins through it. Even so it has to be placed so that it may be photographed. In the studio this can be done on an easel; away from home, anything flat that drawing pins can be stuck into—e.g., the side of a large carton, a wooden box, or even a pastry board—will do. Two pieces of tape are placed tightly across this easel in a horizontal position with two drawing pins at each end (one always comes out at the wrong moment). The distance between the tapes should be about ½ in. greater than the height of the subject. Household pins are then pushed through the tape bringing the points toward edges of the subject to be photographed until the tip of the pins just press flat against it. One pin in each corner (and another in the centre of the tape if the subject is large) will hold the subject without damage, while the ends of the pins—if they show at all—can easily be touched out on the negative.

HOLDING OLD BOOKS. The book page to be copied is set up vertically against the easel, taped down a few pages behind the one required, and the latter clipped with bulldog clips. The horizontal page not being taken is also taped down.

For a book or manuscript page, a board as above is required, the book being opened at right angles with the page to be photographed in a vertical position against the board. Two or three tapes are pinned to the board across the vertical portion of the book, one or two pages behind the one to be photographed, the upper tape being about one inch from the edge. The page or folio to be copied is then laid open and clipped to those held by the tapes with a bulldog clip at each corner. To get the page to lie flat, as the clips are being fixed at each corner, place a piece of clean paper over the page to prevent rubbing or contact with the hand and gently press from the centre of the book diagonally towards each corner to remove any trace of a bulge. If the horizontal page not being taken tends to get in the way, tape will hold it down. A piece of black paper should always be laid on this page to cut out reflected light and prevent uneven illumination At home, a flat subject is best held in an old printing frame, or, if it is a book, in one of the special bookholders made for the purpose. Finally the wedges are used to set the easel absolutely vertical in all aspects.

Lighting. With flat subjects lighting presents no special problems. A pair of lamps are the best source since it is risky to rely on daylight. The lightweight music-stand type of lighting stand is excellent. For the light source, three 200 watt lamps (one spare) of the interior sprayed type are suitable. A length of cable and an assortment of plugs and adapters should be carried.

When working away from home it is as well to find out in advance the voltage where the work is to be done.

One lamp should be placed on either side of the camera and spaced according to the size of the subject to give even illumination over the whole surface. Great care must be taken to avoid reflections from subjects with shiny surfaces; if the lamps are placed too close to the camera there is a danger of reflection from the lamps on the surface of the subject. If reflections do appear, the lamps must be moved out sideways until the reflections vanish.

On the other hand, with an uneven or cockled chart or map, the lamps should be placed as close to the camera as possible to avoid shadows from the irregularities in the surface.

CC-0. Panjab University Digital Preservation Foundation, Chandigarh

The lamps must never be placed so close to the original that the heat from them will cause the subject to curl, as apart from the risk of damage, there is the possibility of the subject moving during the actual exposure.

Exposure. Hard and fast rules cannot be laid down and much depends on experience. There are so many factors to be considered—type and colour of original, reduction scale, type of plate, and lighting—that each subject must be decided on its merits. Even with an exposure meter, allowance must be made when the subject is close. When copying close up, the exposure indicated by the meter should be multiplied by

$$\frac{(\text{camera extension})^2}{(\text{focal length of lens})^2}$$

to arrive at the correct exposure. This is usually more convenient than recalculating the *f*-numbers, which alter when the lens is used at greater than normal extension.

For example: if the meter indicates an exposure of 10 seconds at a particular stop when photographing same-size with a lens of 8 ins. focal length (when the camera extension would be 16 ins.) the correct exposure would be

$$10 \times 16^2/8^2 = 10 \times 4 = 40 \text{ seconds}$$

Old Photographs. These may be of any colour from a good glossy black-and-white to a faded yellow ghost image, or even a combination of both. They may be flat, curled, or even badly cracked and crumpled. In this case, it is as well to try to persuade the owner to allow the picture to be pressed or even reglazed. If reglazing is undertaken the print should be given a light wipe over with cotton wool moistened with carbon tetrachloride to remove any greasy fingermarks.

For faded yellow prints or daguerreotypes a slow process or fine-grain ordinary plate will often work wonders. Orthochromatic plates are usually good for copying the black-and-white and brown tones. Really dark brown or red-brown prints, like dark oil paintings, should always be given a little more exposure than seems necessary.

Maps and Plans. These may be printed in plain line, coloured or tinted. The technique will depend on the colour to be brought out, and its background. In most cases a pan plate with a filter the same colour as the background will produce the desired effect. If the subject is badly stained, but the aim is to reproduce mainly the drawing then a pan-process plate and a red filter are called for.

If a map has to be taken in sections and the resulting prints joined together, the correct technique to avoid difficulty in matching up at the joins is as follows: take the first half, then turn the map upside down and take the second half, without moving camera, focus, or easel. Take four quarters in this order: top left quarter, bottom right quarter; reverse map; take top right quarter, and finally bottom left quarter, keeping the map on the same plane and moving nothing else. A slight overlap should always be allowed at all joining edges.

Manuscripts. Manuscripts to be copied may be paper or vellum and of these, those on vellum usually present the most difficulty. Often they are highly illuminated with a large amount of beaten gold leaf ornamentation. A fine gradation pan plate with a 2× yellow filter will give adequate colour correction. For the gold leaf, the secret is to capture sheen without shine, and a little manœuvring of the lamps is usually all that is necessary. Most owners of this type of manuscript forbid the use of glass over illuminations because of the risk of damage.

Vellum often contains holes which need backing up with white paper. It is important for the backing paper to cover the whole page or it will show through as a light patch. Vellum is also sometimes slightly transparent, and allows any writing to show through from the back. A sheet of black paper behind it will often help, but it will darken the whole sheet and the exposure must be increased accordingly. Lastly, one side of a sheet of vellum is often very different in colour from the other and if several folios are being taken, it may be necessary to allow for this by varying the exposure.

Processing. Normal processing techniques will cover most of the subjects mentioned above. Either contrast or normal developers are appropriate. Tank development may be used for a long series of similar subjects but dish development should always be employed for the more special ones. After two-thirds of the normal development time has gone by, the appearance of the image should be checked visually. The finished print is intended to reproduce the original faithfully and in some cases to bring back to vivid life an image that is fading away. A glance at the right moment will show whether to give a little extra development to increase the contrast or to stop before losing a delicate tint present in the original. D.A.W.

MAREY, ETIENNE JULES, 1830–1904. French physiologist. In 1882, began to use photography to analyse animal and human movements. Muybridge and Marey kept one another acquainted with their experiments

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

and Marey invented a whole series of methods for registering complicated and fleeting physiological actions, notably the ophygmograph for heart action, a photographic gun (1882) for taking serial pictures of birds in flight; and in 1887 his "chronophotograph"; the second model, designed by Marey and Demeny in 1890, used flexible film and is a forerunner of the modern cinematograph camera. In 1892 Demeny and Marey devised the Phonoscope, a projection apparatus for synthesizing motion. Marey also invented slow motion cameras (700 images per second in the 1894 model).

MARINE PHOTOGRAPHY. The sea and its harbours and traffic of ships, yachts and small boats offers a wealth of subjects to the photographer. All these subjects are apart from ordinary photography as the sailor is apart from those who live and work ashore.

The photographer's approach to marine subjects is essentially pictorial; if his results do not convey something of the poetry of the sea and the drama of the life afloat, then he will have missed the most significant feature.

Cameras. The most convenient type of camera for marine photography is the miniature, but it does not necessarily produce the best pictures. It is small, which is an advantage when moving around in small boats, and it will make a series of pictures in rapid succession—a useful point when following groups of small racing yachts.

Then, although there is no difficulty in filling the small viewfinder of a miniature when standing on shore, it is not easy to do it accurately afloat. A slight error in lining up the subject may call for serious cuts in the picture area to get the horizon straight again in the print.

Finally, the negative given by the miniature is uncomfortably small, and when it is enlarged to a reasonable size, such valuable details as the delicate tracery of rigging and the texture of a bellying sail are apt to disappear.

For the serious professional a quarter-plate or even a 4 × 5 ins. camera is a more satisfactory instrument. The smaller amount of enlargement required for the bigger negative means that the essential detail can be preserved even when the subject and camera may both be moving.

Whatever type of camera is used, it must have a direct vision finder. It is extremely difficult to stand up in a boat and look down into a reflex or waist-level finder. With a direct finder, the eye observes the subject naturally and there is no difficulty in maintaining balance. It is always wise to allow a margin around the subject in the viewfinder so that the picture can be trimmed to make the horizon level. This tell-tale horizontal line in marine pictures shows slight errors in lining up that would never be noticed in a normal photograph.

The shutter must be speeded to at least 1/500 second for taking photographs of ships and yachts from another boat. It must be remembered that the camera is on a moving platform. (The fastest sailing boat never moves at more than 14 to 16 knots. At this speed, an exposure of 1/100 second would suffice to arrest the movement if the camera were operated from a steady platform, but a much higher speed is called for when the picture is being taken from another boat.)

One final essential is a really deep lens hood. This serves the double purpose of protecting the lens from flying spray and cutting off stray reflections from the surface of the water.

Filters. A good range of filters is an advantage because of the great variation of tone in sea and sky. It is very easy to under- or over-correct, and any errors will show up immediately.

When photographing sails against the sky, they must appear in their true tone relationship. Seascapes generally need more correction than landscapes, but too deep a filter kills atmosphere and loses the beauty of soft gradation.

A pale green filter and a series of yellow (pale, medium and deep) cover all the normal requirements of the marine photographer. The most convenient form of filter holder is the type that screws into the back of the lens hood; in small craft the photographer must be prepared to "step lively" and a slip-on filter is apt to fall off in the process.

Sensitized Materials. The miniaturist should use nothing faster than a medium speed panchromatic film so that he can retain the advantage of fine grain. In summer the light may occasionally be strong enough to use a slow panchromatic film where there is not a lot of subject or camera movement, but generally it is wiser to use the faster film and cut down the exposure time. The user of a quarter-plate or 5 × 4 ins. camera can afford to stick to the fastest panchromatic plates because at the normal scale of enlargement the coarser grain will not be troublesome.

Seascapes. The light at the seaside is very rich in actinic rays and the scene is mainly made up of blue sea and sky and light-coloured stretches of sand. So everything makes for very short exposures. It is usually advisable to give one-half to one-quarter the exposure that would be given to a normal subject inland.

Photographs taken on the open sea call for even shorter exposures—one-quarter to one-eighth of the exposure for a normal inland view.

Breaking waves and moving water generally should be photographed at a shutter speed slow enough to show a slight blur—i.e., at not more than 1/200 second. A faster shutter speed than this arrests the movement completely and makes the water look stationary and "frozen".

Flat lighting is useless for catching the sparkle of the spray and breaking waves; the

right time to take such pictures is when the sun is shining across, or even slightly towards the subject.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Seascapes call for careful development: over-developing burns out the delicate highlights—e.g., of sunshine on white sails and hulls. A soft-working developer and a leaning towards under- rather than over-development gives the right sort of result.

Harbours. Ports and harbours offer a choice of subject material of such variety that it is impossible to give any general guidance. Since the water is still, however, it is always worth while to study the reflections of ships and spars and cordage for possible pictures. And the subject, whatever it is, should be simplified as far as possible. General views of harbours and craft are apt to be very confused and busy with distracting detail. Exposure should generally be based on the shadows.

When boats are packed tightly together in a harbour, a higher viewpoint will help to sort out the general effect of confusion. Side or back lighting also helps to separate the craft more and prevent their details merging.

There is nearly always plenty of activity worth photographing in harbours. Jobs such as the cleaning of boats or repairing of fishing nets are part of the everyday life in some harbours, and as such are an essential part of the atmosphere.

Equally important as subjects are the local characters to be found in many harbours. It is usually better to photograph these people by candid techniques rather than to ask them to pose.

Yachts. Sailing boats at sea form the most attractive of all marine pictures. These are subjects that can be found at every seaside resort, but the best opportunities occur where there are regular regattas. For the few shillings that it costs to hire a small motor launch, the photographer can make his own choice of groups or single boats, on a long tack with the lee-scuppers awash, or sailing before the wind with spinnakers hoisted and the crews taking it easy. But do not forget that powered vessels must, if necessary, give way to yachts.

Small boat sailing is a highly popular pastime and all around the coast weekly regattas are held by the various yacht clubs. It is not unusual to see starts of twenty-five to thirty ships on the Solent, the Clyde, and many seaside towns, so the photographer who wishes to specialize in this type of subject never need travel far to find his material.

If the photographer is working from a small boat, he will be unable to keep up with the race and should take up a permanent position either at the start or somewhere along the course where the yachts can be expected to sail fairly close.

A point somewhere on the course is generally to be preferred as small boats are apt to be regarded as a nuisance around the start.

Sunshine is essential in yachting pictures; without it, the sails instead of looking white and sparkling will look drab and dead. There is no particular angle from which yachts look best, but when a boat is lying well over it is better to be on the lee side so that the picture will show the deck and crew and not just the bottom of the hull.

So long as the photographer can get as close to the subject as he wishes, there is no point in using a long focus lens. A normal angle lens fairly close to the subject increases its size in proportion to the background whereas a long focus lens makes it look less imposing in proportion.

Shooting from a small boat is a knack that has to be learned. The photographer must stand with feet apart in line with the direction of the motion of the boat. He must keep his balance without supporting himself against a mast or the gunwale because that would increase the movement of the camera. And although the lens hood will keep a certain amount of spray off the lens, the camera should be held in the lee of the body except when shooting.

The best advice that can be given to anyone who contemplates taking photographs from a yacht during a race is—don't. At such times anyone but a working member of the crew is unwelcome, and in any case passengers have their work cut out in keeping out of the way.

Subject Contrast. Photographs near or on the sea tend to be excessively contrasty because of the brilliance of the light and the absence of reflected light in the shadow areas. The contrast can be reduced by exposing fully and cutting the development time, or by using a soft-working developer.

It is not possible to reduce the contrasts of scene by providing a reflector to throw light into the shadow areas. But the same effect can be arrived at by taking the photograph on a day when there are large masses of sunlit white cloud in the sky. At such times the contrasts of the scene are very much lower than when the brilliant sun shines out of a cloudless blue sky.

Exposure. The only safe guide to exposure with subjects at sea in sunshine is an exposure meter and even that must be checked by experiment before the reading can be accepted. On an average sunny day, exposure on a fast pan film with a medium filter will be of the order of 1/100 second at *f* 11, but it will vary according to conditions to considerably more or less than this figure.

Finally, as both sand and salt water are bad for fine mechanisms and exposed metal, the camera should be kept covered up or in its case and taken out only for the shortest possible time when it is absolutely necessary. F.W.B.

MARKETING—PHOTOGRAPHIC GOODS

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The marketing of photographic goods has made rapid strides in the past decade, and the methods of marketing have also varied considerably. The turnover of all kinds of cameras, equipment and sensitive materials has also advanced and the availability and selection of cameras and accessories has extended considerably.

Imports come from Japan, Germany and a dozen other countries. It is estimated that there are over 12 million camera users in Britain, spending over £60 million a year on amateur photography alone. Marketing, therefore, is now a complex operation.

The Photographic Manufacturer. The larger manufacturers supply the photographic dealers direct, either via road or rail, or from warehouses distributed throughout the country.

Photographic manufacturers employ divisional sales representatives to call on dealers throughout the country, and link this up with trade advertising, exhibitions and sales training courses in the selling and use of their more specialized equipment. (British manufacturers sometimes get a price advantage over their foreign competitors, because there is no duty on home produced goods, but both carry the same purchase tax. On the other hand, British manufacturers may have to import raw materials at a greater cost than the price prevailing in some foreign countries, and labour costs may be higher in Britain.)

The manufacturer has many things to consider besides competitive quality and price. For example, with sensitized photographic materials he must also consider right storage, suitable packing and transport and the expiry date of his wares. Any one of these being faulty could have a disastrous effect on his marketing. Providing instruction booklets or leaflets with practically every item is essential. Continued sales depend on proper use of the equipment and material supplied, and therefore photographic manufacturers spend large sums on booklets, lecturers, advertising and sales and technical training to ensure that the dealer who sells them and the customer who uses them know the essentials. The manufacturer who invents and introduces new products may have to build up a possible market for these goods, and this raises total marketing costs.

Some manufacturers may supply the larger dealers direct, and the wholesalers will supply the smaller firms. The marketing of a product by a manufacturer has to be considered well in advance, for, not only must he consider the best time of the year to market the goods, but also the design, price, window displays and counter cards, advertising, packing, quantity to make, and sales policy and distribution.

The Photographic Importer. The job of marketing photographic goods is both comprehensive and skilled, and calls for business acumen of the highest order. Imports from abroad have to go through Customs to be cleared and the appropriate duty paid. In Britain and the United States there are a large number of photographic importers who handle vast quantities of goods during the year, and also pay the duty and see that the right amount of purchase tax is added to the price and collected by them for transfer to the proper authorities.

The photographic importer, having obtained the goods through Customs clearance, then advertises through the trade press and sends sales representatives round to the photographic dealers to get orders for the goods he has to sell. To make the distribution fair and ensure a reasonable livelihood for the importer, the manufacturer abroad usually only has one importer for his wares in each country. When the importer only has a small sales staff, he may also market his wares through photographic wholesalers. The task of the importer is important, for by stocking the various new lines as they become available he is helping to ensure that both professional and amateur photographers have the opportunity to purchase practically any of the cameras and equipment made throughout the world. A good knowledge of photography and photographic equipment is necessary if the importer is going to be able to recognize what will sell and what is really new on the market. He must also decide how much any piece of equipment should sell for to give both him and the photographic retailer a reasonable profit. Importers pay visits to camera works abroad to see the latest models being made, and to discuss with the manufacturers future likely demands and markets. (The photographic importers in Britain have their own Association—The Photographic Importers Association—which looks after their interests and welfare.)

While the average-sized photographic importer may only handle the goods, the larger ones may employ skilled staff to check the goods and skilled repairers for any equipment which proves faulty and which is covered by their guarantee. The photographic importer also has heavy insurance and security charges to meet.

The Wholesaler. Wholesalers throughout the country offer a good service to the photographic dealer, and particularly to the smaller dealer, who is in this way enabled to keep a small but comprehensive stock, and obtain quick local deliveries. The wholesaler fulfils another useful function in taking a considerable quantity of the maker's stock, thus helping the manufacturer's storage problems. Photographic wholesalers usually have a sales staff to cover specific areas but the larger ones cover the whole country.

The Retailer. It is through the photographic retailer that the final link in the marketing chain comes to fruition, for he meets the members of the public and is in direct touch with public demand. The photographic dealer and his assistants have to be knowledgeable and quali-

fied people. Whereas there used to be but a few pieces of equipment to sell, today the dealer needs to know something about the many different types of cameras and accessories available and their manifold uses.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Photography is now used for many purposes, including medicine, science, aerial work, research, publicity, forensic medicine, astronomy, photomicrography, micro-photography, document copying and many more. The photographic dealer is expected to be able to advise the prospective customer on the equipment he needs, show him how to use it correctly, criticise his results, and help him to obtain improved results.

The photographic dealers in Britain are divided into three groups: the purely photographic dealer (who sells photographic equipment only); the chemist; and the photographer/dealer. The sizes of the firms may vary and whereas one dealer may sell films and the cheaper range of cameras and equipment, another may sell every type of equipment, and have projection theatres and special departments and assistants for specialized goods. The processing of films is now rarely done by the photographic dealer, but by a "finisher" who collects and delivers films for processing, and deals with both black and white and colour materials.

Staff training for dealers' assistants has become a necessity today. In Britain, assistants can take courses sponsored by The Photographic Dealers Association and a number of the larger manufacturers, or take courses at technical colleges in London and the provinces.

The cameras and equipment the photographic dealer has to sell today are supplied in the greater part from abroad, and nearly all this equipment carries a fairly high import duty and purchase tax. Thus the selling prices of equipment are higher in Britain than in most countries abroad. In Britain, photographic films and paper are made by several large firms in bulk, and some specialized photographic equipment is made, but the popular-sized still cameras and cine cameras and projectors are made abroad.

There are fewer photographic retailers per head of the population in Britain than elsewhere.

For example in Britain there are approximately only twenty photo dealers to each million of the population, while in Switzerland there are about 150. Other countries of Europe, e.g. West Germany, France, Denmark, Sweden, Belgium and Holland, have about sixty photo retailers to every one million of their population.

The business of selling cameras and equipment is still booming, and providing there is no recession of trade—or unemployment—it should continue for a large number of years. The production of photographic journals and text books has also undoubtedly increased the trade of the photographic retailer. A.Pg.

MARKING UP. Technique of indicating final size and other details (cutting, retouching, etc.) on an illustration to be reproduced for block-making or other purposes.

See also: *Scaling for reproduction.*

MARTIN, PAUL, 1864–1942. English wood-engraver and photographer, known chiefly for his candid shots taken in the 1890s with a concealed hand camera in London streets and at the seaside. 1900–1908, worked as a free-lance press photographer; thereafter as a process engraver in London. His photographs of London by night, 1895–6, were the first of their kind. *Victorian Snapshots* by Paul Martin, (1939).

MARVILLE, CHARLES. Dates unknown. French photographer to Museums. In the 1850s he recorded the quarters of Paris to be pulled down to make way for the boulevards of Haussmann.

MASER, OPTICAL. Light source of special characteristics depending on stimulated emission of radiation. Maser stands for microwave amplification by stimulated emission of radiation, derived from micro wave communication, but also applicable to light waves—hence the description "optical" maser. Nowadays generally known as a laser.

MASKING

Photographic masking of any kind is essentially the technique of interposing a mask—something which will reduce the quantity of light—in the path of the light forming an image and thus modifying the photographic result. As a simple example, holding the hands, or a piece of card, over part of the image in an enlarger for part of the exposure, masks the print. However, it is more usual in these days to limit the term to the use of a photographic image for that purpose and to use the word mask whether the image is positive, negative, a colour separation record or, indeed, a coloured record.

MONOCHROME MASKING

The method is used in this case almost invariably to reduce contrast, although not necessarily over the whole of the image. Consider the simplest case; a negative may have a good tone range, but too high contrast for convenient printing on the required material. The way to solve the problem is to make a very

CC-0. Agamnigam Digital Preservation Foundation (Chennai)

MASKING FOR CONTRAST. 1. A very contrasty negative may not record all tones on printing paper (limited contrast range shown by height of "staircase"). 2. To overcome this a low-contrast positive is made. 3. This is bound up with the negative, and reduces the tone range, enabling the paper to reproduce all the tones within its own contrast range.

weak and soft, but full-toned, positive contact print from the hard negative on another plate or film. When dry, this is bound into contact in accurate register with it. The mask will then tend to cancel out the negative and it will have the effect of considerably reducing the contrast of the negative, which may be very useful.

Selective Masking. In industrial photographs where often a machine, or other object, has to be photographed in a workshop against an obtrusive background, masking is a useful alternative to blocking. It permits the presence of the other machines to be shown in subdued tones.

The method consists of painting out the machine with opaque on the original negative. This is then contact printed on a plate and under-developed so that only the shadow tones of the background machines are weakly recorded. When the mask is dried and bound back in register with the negative (from which the opaque has been washed off), it prints with the shadow tones of the background reduced in weight. The background is still visible but is less obtrusive and the important machine stands out satisfactorily. The mask can be made to a suitable density to cancel out the background to any required extent.

Masking for Tone Control. Often the important tones of a photograph lie at the highlight end of the range (a bridal dress, for example) or at the shadow end (a railway engine, for example).

The negative of a predominantly light toned subject will usually record the highlight detail best on a more contrasty grade of bromide paper, but the shadow tones are then much too black. This can be overcome by masking the shadow tones by means of an under-exposed mask which records only the lower end of the range. A print is then possible on the more contrasty bromide paper which stretches out the highlight range considerably. Of course there is a commensurate loss of shadow detail, but at least the shadows are no longer too dark and the gain in highlight quality can be quite remarkable. (Uneven flattening in tone range can even be an advantage in some cases.)

At the other end of the scale, boosting the shadow quality is best tackled in two stages. The initial negative of the subject should be fairly soft and thin; that is to say, fully exposed and not fully developed.

The first stage of the masking operation is the production of a fairly soft contact positive on film of much the same quality as used for highlight improvement above. When that positive is dried a plate is exposed against the back of it and developed to produce a soft and very thin laterally reversed negative having detail in the shadow tones and an over-all even density of about 0·3 in all lighter tones. When

MASKING FOR TONE CONTROL. 1. Contrasty negative may record full tone range on soft paper, but result looks dull. On normal paper rendering is better, but some tones (e.g., shadows) are lost. 2. A low contrast positive mask of shadows only is made. 3. Bound up with the negative, this compresses shadow gradation without flattening highlights. Uneven compression of tone range yields better print.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SHARP AND UNSHARP MASKING. Left: *Sharp mask. 1. Mask made by contact exposure. 2. Negative and mask bound up. 3. Resultant density reduced.* Right: *Unsharp mask. 1A. Mask exposed with spacer between negative and positive. Blurred mask outlines larger than on negative. 2A. Negative and mask bound up. 3A. Density reduced; blurred mask outlines also cancel slight edge blurring of negative image, resulting in an appearance of increased sharpness.*

the negative mask is bound up in register with the original negative the shadow tones are emphasized by the mask and all higher tones are evenly raised in density. There is thus a gain in total density range and the gain in quality is all in the lower end of the tone scale. This is an exception to the generality of masking effects because of the increase rather than decrease in density range; it works very well in practice.

Unsharp Masking. Most masking methods may be used with sharp or unsharp masks. It is claimed that unsharp masks improve the rendition of detail, which may seem a contradiction. What happens is that the blurred outline of the unsharp mask ("thickened" would be a better term) tends to cancel the slight blurring of the outlines that is present even in a nominally sharp negative. In effect it outlines each small piece of detail so that it does, in fact, become more plainly visible. In practice the visual effect is a general one of apparently greater sharpness; the outlining is too delicate to be seen in detail with the naked eye.

A suitable method of making the mask is to use a fairly small light source and to suspend it, at an angle, some distance above the contact frame in which the mask is printed. A thin sheet of transparent plastic (a spacer) is used between the negative or positive from which the mask is being printed. The printing frame revolves on a rotating table throughout the exposure.

COLOUR MASKING

Any colour print or transparency can be masked, when it is copied, in any of the ways described for monochrome masking above, but there is also the possibility of colour masking which offers considerable advantages in improving the colour reproduction and compensating for deficiencies in the colours used.

In theory, the yellow, magenta-red, and cyan-blue tricolour printing colours forming the image of a colour transparency or colour print should each perfectly transmit (or reflect) two-thirds of the spectrum of white light. The yellow should transmit the whole of the green and red from about 4,900 Angstrom units to the limit of vision in the red (around 6,800 A.), completely absorbing the remainder. The magenta-red should transmit the whole of the blue and the whole of the red from before the beginning of the blue (around 4,000 A.) to about 5,100 A., and from about 5,900 A. to about 6,800 A. at the visual end of the red, with a gap of absorption between them. Finally the cyan-blue should transmit the whole of the blue and green from about 4,000 A., to about 6,100 A. at the beginning of the orange-red, absorbing the remainder.

Unhappily only the yellow printing colour is really efficient; the magenta-red is fairly efficient in its red transmission, but very poor in the blue, also it does not absorb green as

COLOUR MASKING. 1. Transmission of ideal magenta. 1A. Corresponding spectral density of green filter negative. 2. Actual magenta dye. 3. Theoretical modification required to add to dye transmission. 3A. This corresponds to a weak positive from the red filter negative. 4A. Red filter positive added to green filter negative, yields approximately result 1 with an imperfect dye of characteristics 2.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

well as it should. The cyan-blue transmits blue only fairly well and green poorly; indeed that is the reason why magenta is commonly called "red" for it is not blue enough and cyan "blue" because it is not green enough. One might suppose that a magenta-red might be improved by adding blue to it, but that would reduce the red reflection and cannot be done. For much the same reason cyan-blue cannot be much improved. There are better magentas and cyans, but unfortunately they are fugitive and cannot be used.

In terms of percentage, on a basis of calling the total amount of blue, green and red reflected by good white paper 100 per cent of each, an excellent yellow may transmit 90 per cent each of green and red. However, magenta-red transmits 90 per cent of red and less than 40 per cent of blue, while cyan-blue transmits less than 75 per cent of blue and not more than 50 per cent of green. It is basically for this reason that the colour printings of any colour reproduction need to be colour corrected either by hand or by colour masking.

The colour filters used to take the colour separations or the responses of the three layers of transparency materials are qualitatively quite efficient and their quantitative faults can be dealt with by increasing the exposure time or the sensitivity of tripack layers; it is the printing colours which are the difficulty.

These deficiencies can be compensated by increasing the density of the corresponding negative image portions responsible for that colour. Thus a positive mask from the red filter negative will correspond to a cyan density. When bound up with the green filter negative this will make up for the shortcomings of the cyan in the original transparency as recorded on the green filter negative.

Similarly a weak positive mask from the unmasked green filter negative corresponds to a magenta density, and when bound up with the blue filter negative will make up for the lack of magenta as recorded on that negative.

In general, therefore, it may be said that, whether one is masking negatives or positives (with positives or negatives respectively) a mask from the red filter record is bound up with the green filter record and a mask from the green filter record is bound up with the blue filter record. The red filter record is rarely masked (or perhaps "self-masked" with a record from itself to keep the density range constant with the others). If the red filter record is colour masked at all it should have an extra weak mask made from the blue filter record.

Colour Masks in Practice. Amateur photographers are likely to use colour masking only when making colour prints from colour transparencies. For that the method is most valuable because transparencies are almost invariably too contrasty for direct colour separation negative making and in addition require colour correction. The Murray contact masking technique usefully serves both purposes. In essence it requires the following stages.

(1) A highlight mask (necessary if there is bright highlight detail): a film to film contact negative print is made from the transparency, on a contrasty panchromatic plate (usually with a red filter, or low wattage bulb and no filter). This is so under-exposed that only the top highlight records at a density of the order of 0·4, as read on a densitometer. When that highlight negative is processed and dry the transparency is bound into accurate register with it by means of cellulose tape. After that the colour masks are made by contact printing them from the sandwich.

(2) The colour masks: the transparency being bound, film down, upon the highlight mask, a contact colour mask is then made by exposing a normal contrast panchromatic plate in contact with the back of the transparency. The printing frame should stand on a rotating base and a red filter used over the fairly small light source. The red filter mask should have a minimum density of about 0·2 and the range from minimum to maximum density should be about 40 per cent of the density range of the transparency.

This is repeated with a green filter record which should have a minimum density range of about 0·2 and a range of about 30 per cent of that of the transparency.

(3) The separations: when the two colour masks are made the highlight mask is no longer required and is dispensed with.

The transparency is then bound into register first with the red filter colour mask (so that it is thus film side out). With that combination of transparency plus mask, both the red filter (cyan-blue printer) and the green filter (magenta-red printer) separation negatives are made by contact or projection on normal contrast panchromatic plates.

If a four-colour print is required (that is, with a black printing in addition to the colours) a fairly successful result can usually be obtained by using a yellow-green filter through the transparency plus red filter mask combination. The black printer is, however, always rather a problem and is best treated according to the main colours of the subject, often by exposures through each tricolour filter in turn, with modification of the timings.

In the case of the red filter exposure, for the cyan-blue printer separation, the mask serves only to reduce the high contrast of the transparency to a convenient level. The mask is itself a red filter record, and the result is said to be "self-masked".

But in the case of the green filter exposure, for the magenta-red printer separation, the effect of the mask is different. It usefully lowers the contrast range, but it also modifies

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the result selectively. In fact, it will be found that the blue and green colours of the transparency are recorded in the negative as much denser than usual, while red colours are recorded more transparent than usual. Therefore the magenta-red print from the negative is strong in the red colours and much weaker in the blues and greens—which is precisely what is required and would have to be contrived by hand retouching if not by this automatic photographic means.

Once the cyan-blue and the magenta-red printer negatives (and perhaps the black printer) are made, the transparency is removed from the red filter colour mask and registered on the green filter mask, that combination being used when making the blue filter (yellow printer) negative.

The density range of the separation negatives is, of course, governed by the printing process for which they are made (carbro, dye transfer, etc.). In general the minimum density should not be much less than about 0·5 and the range from minimum to maximum probably of the order of 1·0 for dye transfer and rather less for carbro according to the type of sensitizer that is being used.

Step Wedges and Colour Patches. Among very experienced colour workers there is some controversy about whether a step wedge laid beside the transparency should be recorded identically in each record of a colour set. In any case a black-to-white step wedge should always be included and colour patches are also useful, both for identifying the separations and for checking the success of the printing. A very expert worker might vary the contrast of the record of the wedge in one or more of the separations, especially if he wished to make some modification of the effect in the print. But until a great deal of experience is gained, it is best to aim to make all the separations so that the density range and quality of the record of the step wedge is as precisely matched as possible throughout the set.

Masking Positives or Negatives. The above description relates to the masking of positive transparencies with negative masks. Fortunately the same technique works equally well for the masking of negative subjects with positive masks. For example, a colour negative for one of the colour negative-positive processes can be masked exactly as described for a positive colour transparency. That is, a red filter mask is used for making both the red filter positive (in this case) and the green filter positive (perhaps also the black printer), while a green filter mask is used when making the blue filter positive separation.

Furthermore the same basic principle can be used for a set of separation negatives which are to be colour masked when making positives (for example for printing the reliefs for dye transfer).

A negative range of around 1·0 is suitable for printing dye-transfer positive reliefs, depending somewhat on whether printing is by contact or projection and the type of enlarger in the latter case. (For contact printing the masked negatives the initial negatives must be on film, which is quite possible in these days of dimensionally stable film bases, and the masks must be made in contact with the backs of the negatives.)

The masked negatives must have a range of 1·0 which means that the initial separation negatives must be a good deal more contrasty to allow for the reduction of contrast by the masks. Suitable figures may be 40 per cent of the contrast range for the red filter mask and 30 per cent for the green filter mask. To suit those requirements the initial red filter and green filter negatives should have a range of 1·6 (say from 0·3 to 1·9) while the blue filter negative should have a range of 1·4 (from 0·5 to 1·9).

The two colour masks (preferably unsharp) are then made by contact from the red filter and green filter negatives, the mask from the red filter negative having a range from 0·8 to 0·2 and the mask from the green filter negative having a range from 0·6 to 0·2. (The densities are quoted as from shadow to highlight so that the effect of negative plus positive is obtained by simple addition.) The red filter mask is then bound up into register, first with its own red filter initial negative (thus self-masking it) and printed, then with the green filter negative and printed. The green filter mask is used on the blue filter negative. The total density range of negative plus mask totals in each case from 1·1 to 2·1 which is 0·6 higher than the normal colour separation negative range of from 0·5 to 1·5. So the masked negatives will require four times the normal exposure (antilog 0·6).

PROFESSIONAL MASKING

An extremely wide range of masking methods, both for monochrome and colour are used in practically all branches of professional photography. One absolutely invariable feature of all such work is the extremely precise sensitometric and densitometric control which is always employed: empirical methods are entirely inadequate.

The cine industry uses masking to a great extent. Processes range from simple back projection methods, where the actors performing before the projected background mask out portions of it (because they are solid), to all the intricate matte processes. These are used in combining two or more negatives of parts of the complete picture when making the prints for projection in the cinemas. By these methods it is possible to avoid sending actors on expensive location shooting.

Complete colour masking controls are also employed in the preparation of colour motion pictures.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Masking in the Graphic Arts. Masking is used to a continually increasing extent in the processes employed in the preparation of printing surfaces of all kinds.

The basic essential for many of the processes is mechanical means of inserting and replacing masks and other negatives or positives into precise register so that a number of different masking exposures may be made on one photographic plate. The best known of these is a special make of masking camera on which a great many different masking techniques can be undertaken with certainty of precise register. On this camera a negative or positive of large size can be contact printed with light which proceeds from a much smaller mask so that the exposing light is itself masked. The contact print is therefore modified as required for colour masking or for such purposes as the introduction of lettering into the picture or the formation of a montage. A different approach to somewhat similar problems is one make of supplementary camera, which can be fitted to a process camera and projects masking images into the image plane via a transparent pellicle mirror.

Integral Masks. One firm's integral mask invention as used in their own colour negative-positive process is useful both for graphic arts and for pure photographic colour print making.

According to this idea the middle (magenta-red printer) layer of an integral tripack transparency material contains a weak orange-yellow dye and the bottom (cyan-blue printer) layer contains a weak red dye before the material is exposed. The colour-development of the material dissipates the dyes in the situation of the respective images. The result is a colour negative which already has its green filter record and red filter record positive masks automatically within it. Therefore when the colour negative is printed by contact or projection on integral tripack material on a white base it yields an automatically colour-masked print. If colour separation positives are made they also are colour masked. Those separation positives may be used for graphic arts reproduction or, if they are in the form of dye-transfer reliefs, for paper print making.

Coloured Masks. A development of colour-masking principles is the idea of making the colour masks themselves coloured, so that they have different effects upon the colour separations according to the colour of the filter used to make the exposure through the mask.

One of the first of these methods used three bi-pack films, each effectively two-thirds of a tri-pack colour transparency film. Thus one film is sensitive to blue and green light in its two layers, and colour-develops to yellow and magenta respectively; the second film is sensitive to blue and red light and colour-develops to yellow and cyan; the third is sensitive to green and red light and colour-develops to magenta and cyan respectively.

Consider the first of those bi-pack films, when contact printed beneath a positive colour transparency. The top, yellow layer of the transparency is "minus blue" and so provides a negative image in the top, blue-sensitive, layer of the bi-pack material. Similarly the middle, magenta-red, layer of the transparency is "minus green" and so provides a negative image in the lower, green sensitive, layer of the bi-pack material. But the top layer of the bi-pack develops to a yellow negative image which cancels out the yellow positive image of the transparency; similarly the lower layer of the bi-pack colour-develops to a magenta-red negative image which cancels out the magenta-red positive image of the transparency. Thus, when the processed and dried bi-pack colour negative mask image is bound up in register with the initial positive colour transparency, it cancels out the yellow and magenta-red image layers and the combined result appears as a black positive image of the cyan-blue layer of the transparency in a red ground. This can be photographed with red light to produce a colour separation cyan-blue printer image of the cyan-blue layer of the colour transparency, cleanly separated from the yellow and magenta-red layers. Similarly, by using the other two bi-pack film masks, one can obtain a colour separation of the yellow and of the magenta-red layers of the transparency.

A further step are the current tri-pack colour masking films, the three (sometimes more) layers of which develop to the appropriate colours to serve as masks according to the colours of the filters used to make the colour separation images. A simplified example shows the principle.

Suppose a colour tri-pack film material is sensitive, as usual, to blue light in the top layer, to green light in the middle layer and to red light in the bottom layer. But suppose that the three layers colour develop, not to the normal yellow, magenta and cyan colours in the respective layers, as with a normal colour transparency material. Instead, the colours produced are cyan, yellow and magenta, at around half normal strength. If such a material is contact printed beneath a positive colour transparency and developed directly to a colour negative image, the result looks peculiar, but provides a colour-mask which fairly efficiently colour corrects all three of a tri-colour separation set and, indeed, also the black printer of a four-colour set.

Thus the bottom, magenta coloured negative image (formed by red light from the transparency) acts as a colour-mask for the green filter separation negative. This is because magenta is a "minus green" colour, and the yellow and cyan-blue image layers above it would not affect that separation because they both freely transmit green light.

Similarly it can be shown that the yellow middle image layer of the coloured mask (a

"green filter" record) masks the blue filter (yellow printer) separation, according to the general principles of colour-masking, and the top (blue filter) cyan coloured image layer acts as a mask for the red filter (cyan printer) separation.

CC-0. Agamirza Digital Preservation Foundation, Chandigarh

This description shows the general principle of the coloured colour-mask systems. In practice the various makes of the film are somewhat more involved, and they can be used for colour-masking both contact and projection separations of colour transparencies, and also for the camera colour separation of opaque coloured copy.

Electronic Colour Masking. A great deal of research is going on in the use of electronic principles for colour masking.

The methods rely on the fact that photo-electric cells can be made which will respond to some or all of the visible spectrum. It is therefore possible to scan a colour object, print or transparency, with three photo-cells each sensitive to a different portion of the spectrum. They can then each control a fluctuating light spot and produce three or four colour separation negatives or positives.

It is possible to cause part of the impulse from one or more of the cells to be shunted into the circuit of the others and so to introduce colour masking to a practically unlimited extent. Such methods can be used for pure colour photography, of course, but also the impulses can be caused to engrave printing plates direct.

The principle is used in a variety of ways. For instance, there is a device used on a process camera by which an opaque coloured copy, on the camera copyboard, is scanned by a moving spot of light. The intensity of this spot is controlled by the instantaneous response of three photo-electric cells examining the quantities of red, green and blue light reflected by the different colours of the copy. During the scan, which takes several minutes to cover the copy, the camera lens is left open. A colour filter over the lens ensures that one colour-masked colour separation negative is recorded on a panchromatic film or plate in the image plane. The computer portion of the apparatus is then set for the next colour separation, and the copy is light-scanned again, and so on for all four of the separation set.

Another method resembles that of photo-telegraphy but in this case a colour transparency is placed around the transparent cylinder of the portion which may be considered the "sending" part of the apparatus. The cylinder revolves and a very small spot of light shines through the transparency from within the cylinder. The light head slowly moves along the axis, so that the whole of the transparency is "scanned" by the light spot. Three photo-cells measure the quantity and colour of the light spot transmitted through the transparency. The electronic computer portion of the apparatus introduces colour-masking, under-colour removal, tone correction, etc. and feeds four lamp heads. These project four separately modulated points of light upon four films placed around the cylinder at the other end upon which the yellow, magenta-red, cyan-blue and black printer separation negatives are formed in unison with the track of the scanning spot.

Again, there are electronic machines which scan opaque coloured copy or a colour transparency and simultaneously engrave, into a plastic or a metal, a colour-masked, colour separation, half-tone printing plate, the operation being repeated for each of the four separations. If the image is engraved into a transparent plastic having an opaque or a red surface, it may then be printed-down upon a litho plate for that process.

A difficulty of the above three methods is that the various machines usually cannot cope with opaque and transparent subjects of all sizes from miniature transparencies perhaps to a large carpet, for example. Some inventors have approached the problem by designing apparatus into which one places an uncorrected set of continuous tone separation negatives or positives and, by the electronic scanning system, a continuous tone or a half-tone screened set of colour separation positives or negatives is produced, either one at a time or all four simultaneously. F.H.S.

MASKING FRAME. Paper holder for enlarging to keep the paper in position on the easel. Usually also produces a white border round the print. The border and the size of the image area framed may be adjustable.

See also: *Masks; Paper holder.*

MASKS. The appearance of most prints is enhanced by a neat white margin produced by masking off the border of the paper during printing. If the print is made on double weight paper large enough to leave a wide border, it can take the place of the usual mount. The normal mask is rectangular or square in shape, although at one time other shapes were popular (notably circles and ovals).

White Borders. A permanent mask can be built up on the negative with strips of adhesive black paper. Passe partout binding or lantern slide

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

binding strips will serve for this purpose. Care must be taken to keep the corners truly square by checking with a set-square and ruler.

Ready-made masks cut from opaque black paper can be obtained in various shapes, and of different sizes for both prints and lantern slides. These are mostly used for contact printing. If numbers of prints are being made it is a good plan to attach the mask to the front of the negative with transparent self-adhesive tape. This saves constant readjustment each time a fresh piece of paper is inserted.

For contact printing, transparent ruby masks cut from celluloid are available and are preferable to paper masks, being more durable and easily handled. They also facilitate positioning of negative, paper and mask in the contact printer because the actual details of the negative can then still be seen through the mask.

These masks can also be used in contact with the negative when enlarging.

Lantern slide masks are supplied with openings of various sizes and shapes, but domes, cushions and similar fancy shapes are not in favour to-day. These masks are generally made of black paper, although some makes—particularly in 35 mm. size—are also available in metal foil. Masks are also supplied ruled with white guide lines so that the user can cut the shape he desires to suit the subject.

The simplest method of masking a lantern slide is to build up the rectangle with strips of lantern slide binding before adding the cover glass. Or the mask may be attached to the cover glass in the same way. This method affords additional protection against breakage.

Masking Frames. When making enlargements the usual method of masking is to use a masking frame on the baseboard of the enlarger. A masking frame consists of a metal frame made from strips of metal from ⅛ to ¼ in. wide. The frame is hinged to a baseboard so that it can be lifted up to allow the paper to be placed in position. Metal pegs or guide strips are fastened to the baseboard along two adjacent sides of the paper area to allow the sheet of printing paper to be accurately located under the mask. The baseboard is usually painted a dull white and the frame a dead black so that the image can easily be focused and composed before inserting the paper.

MASKING FRAME. The sliding strips adjust the picture area, and the hinged frame holds the paper in position on the baseboard. Adjustable margin stops may be provided.

Adjustable masking frames of this type have two sliding members of black metal strip which form two adjacent sides of the mask. The other sides are formed by the metal frame that carries the sliding strips. Any size of mask up to the full size of the frame can be produced by adjusting the position of the strips on the side members of the frame. They are so mounted that, while they will slide easily, they always lie square to each other and parallel to the corresponding rigid sides of the frame.

On some models, the paper locating strips are themselves also adjustable so that the width of the border can be varied.

Frames of this type are made heavy enough to stay in position on the enlarger baseboard once they have been set to mask the projected image. They serve the double purpose of masking the paper and holding it flat. Some workers use fixed masks consisting of glass plates of a range of different sizes with a border formed with strips of passe partout binding.

Black Borders. It is sometimes effective to give the print a narrow black border. All that is necessary for this is a sheet of metal or a glass plate covered with opaque black paper a quarter of an inch or so smaller in length and width than the finished print. After the print has been exposed, the opaque mask is laid in position under pressure leaving a uniform margin of the print exposed all round, and the white light switched on for a few seconds. The same result can be obtained by trimming the negative to the bare image size and printing it with a clear strip showing along all four sides of the paper, but the result is not as sharp as that given by a mask.

Trick Masks. In addition to the normal type of mask which gives a white border, various trick shapes are used when appropriate.

Oval and circular masks are useful when the corners of the negative are unsharp. A circular mask is easily marked out with a compass, but an oval mask calls for a special technique. The easiest way to mark out an oval is to use two pins stuck into a board at about three-quarters to two-thirds the length of the negative apart. A loop of string is placed over the pins and the length adjusted until a pencil held upright inside the loop cannot quite reach to the top or bottom edge of the print. If the pencil is now moved around so as to keep the loop of string taut it will trace out an oval. The dimensions of the oval can be adjusted by varying the spacing of the pins and the length of the loop. Once the oval has been drawn on the masking paper in this way, the blank can be cut out with a sharp razor blade.

Other shapes popular for trick effects are keyholes, "binocular" openings, and jagged edges suggesting that the subject has broken through the paper. Binocular openings in the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

form of two overlapping circles might be used to give atmosphere to a long narrow landscape view of a horse or yacht race so long as the mask does not cover an important part of the subject.

Many of these fancy shapes are more effective if they are reversed—i.e., to give a black instead of a white masked portion. This is printed in the same way as a black border, using the blank cut out from the centre of the mask to cover the centre of the print during the second exposure to white light.

There are various other ways of producing special masking effects. One effective method is to cover the glass of the frame with sand, sugar, rice, cotton wool or any loose substance, and clear away the area to be printed. This leaves a rough edge with a texture depending on the substance used. The same idea can be used to produce a black border by clearing the masking substance away from the edges and giving a second exposure to white light.

If a soft edge to any type of mask used in contact printing is required, it can be produced by supporting the mask on a sheet of glass above the printing surface. The softness can then be imparted by moving the light during printing. In enlarging the light cannot be moved to soften the edge and the simplest method is to use a mask under the negative, interposing a sheet of glass between the two to throw the mask out of focus.

Cutting Masks. It is not difficult to cut masks; the requirements are thin black paper—e.g., the wrappings from bromide paper—a sheet of glass, a steel rule and set-square, and a print trimming knife. The knife must have a keen cutting edge or the paper will be torn rather than cut. The method is as follows:

Place the paper on the glass and with the steel rule and square mark out the rectangle to be cut with a pencil line. It is a good plan to lay the negative or slide over a sheet of graph paper; the limits of the edges required can then easily be noted with a pencil mark and transferred to the black paper. To cut the mask, rest the knife against the edge of the steel rule, press it firmly down at the beginning of the cut, hold it straight, and cut along the whole of one side of the mask in a single stroke. If the cut is made in more than one stroke there will almost certainly be an irregularity in the edge of the mask.

R.M.F.

MASS MINIATURE RADIOGRAPHY. Mass miniature radiography is a special branch of medical radiography used for making a preliminary X-ray examination of the chests of large numbers of people. It aims at detecting the signs of pulmonary tuberculosis or other chest diseases in its early stages so that the disease can be tackled in good time.

Method. To take a miniature radiograph, the subject is placed with his back to an X-ray tube and his chest against a fluorescent screen. When the X-ray tube is switched on it produces a visible radiographic image of the subject's chest on the screen by fluorescence. This image is photographed on 35 mm. film by a miniature camera focused on the screen. If the miniature radiograph shows any dubious areas the subject is then given a normal full-scale radiographic inspection using large-size X-ray films and equipment.

Equipment. The first equipment used consisted essentially of an X-ray unit, fluorescent screens, and a camera using 35 mm. film, all three being connected together by a light-tight hood; the camera usually had a lens of aperture *f* 1·5. This type of equipment has largely been replaced by units with a mirror-lens system, and an effective aperture about *f* 0·75, in order to reduce the X-ray exposure to the patient. The size of film employed for recording the fluorescent image is now mainly 70 mm. or 100 mm. in width, in single square sheets or in rolls. The fluorescent screen emits either yellow-green, or blue, light so that the sensitivity of the film must be selected accordingly.

Equipment for mass miniature radiography is designed to be relatively easy to transport and operate. Many M.M.R. units are completely self-contained, and have their own transportable generators and darkrooms.

Subject Identification. Each person to be examined is given an identification card on which he fills in his name and address. This card is inserted in a slot in the unit, and the serial number thereon is projected optically on to the film during the exposure. It is therefore impossible for anyone to be associated with the wrong radiograph.

The staff operating the equipment work from behind screens to shield them from unnecessary exposure to the X-rays. A trained team can deal with as many as 600 people per day.

FLUOROGRAPHY SET-UP. The patient is interposed between the X-ray tube and a fluorescent screen which is in turn photographed with a miniature camera.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Organization. In addition to the actual operating staff, an M.M.R. service needs its own administration for arranging mass examinations, identifying negatives, interpreting the results and following up positive cases.

M.M.R. teams regularly tour the country and it is possible for anyone who wishes to have his chest radiographed at the recommended 12-monthly intervals. G.T.S. (C.S.)

MASTIC VARNISH. Varnish (principally for negatives) prepared from the resin exuded from the stems of the Pistacia Lentiscus. The resin is insoluble in water but soluble in alcohol and a number of other spirits and oils.

MATRIX. Relief image used for making dye or pigment prints by transferring colour from the raised parts of the relief to a suitable paper or other base. In photography, gelatin matrices are employed for special processes such as dye transfer colour printing. These matrices are generally made by developing an exposed silver halide emulsion in gelatin with a tanning developer. Alternatively, a photographic image in a gelatin emulsion may be bleached in a tanning bleacher. Either method selectively hardens the gelatin, allowing the unhardened parts to be washed out in warm water, leaving the gelatin relief.

It is usual for the exposure to be made through the base when making a matrix.

MAXWELL, JAMES CLERK, 1831–79. Scottish mathematician, physicist and natural philosopher. Author of valuable investigations on the perception of colour. Demonstrated the fundamental basis of three-colour photography (1861). His researches established the electro-magnetic theory of light. Biography by Campbell and Garnett (2nd edition 1884).

MAYALL, JOHN JABEZ EDWIN, 1810–1901. American daguerreotypist. Worked in Philadelphia (1842–6), London (1847–66) and Brighton. Introduced from France the albumen glass negative process in 1851. Also patented Ivorytype, 1855. Leading professional in the carte-de-visite period, which he made popular in England in 1860. Introduced the carte album in the same year.

MEASURE. Graduated containers for measuring volumes of liquids, and sometimes solids.

Most measures are glass or plastic beakers or tumblers with a scale marked down one side. They may be cylindrical or conical in shape; in the latter case the interval between the scale divisions is necessarily greater near the bottom than at the top.

Measures for large volumes may be in the form of plastic or enamelled jugs.

Scales. Measures may be graduated in metric units (cubic centimetres or millilitres and litres) or in Imperial fluid measure (minims, drachms, fluid ounces, or pints). Sometimes a measure carries graduations in both systems.

Sizes. Small measures hold 1 or 2 ounces, subdivided in drachms and tens of minims; or 25–50 c.cm., subdivided in c.cm. (scientific laboratory glass-ware is almost always graduated in millilitres). They are used to measure out stock solutions for dilution, etc. Intermediate sizes hold 4 to 20 ounces (or 100 to 500 c.cm.) to measure out larger quantities such as working solutions required to fill a developing tank. The largest measures may hold 40 or more ounces (1 litre upwards) for filling larger tanks.

Accuracy. Cylindrical measures in the small sizes are expected to be accurate to the nearest 0·1 c.cm. or to the nearest 2 minims. With a 100 c.cm. or 4 ounce measure an accuracy of 1 c.cm. or ¼ drachm is quite sufficient, and many measures are considerably less accurate than that. An accurate 500 c.cm. or pint measure should measure to the nearest 5 c.cm. or drachm.

The accuracy depends both on the shape of the measure and on the method of calibration. The most accurate types are the cylindrical and conical measures calibrated individually by an engraved scale. Tumbler and other measures with etched or painted scales are still reasonably accurate for most photographic purposes.

Plastic measures with embossed graduations are as accurate as any glass measures of the same size, as the moulds can be made with a high degree of precision.

Enamelled jugs with painted or enamelled-on scales cannot be expected to measure more exactly than to the nearest ½ ounce in the 20-ounce size.

Burettes and pipettes may be used for measuring small volumes with particular accuracy.

Reading the Scale. The correct level from which to read a volume of liquid is the bottom of the

READING LIQUID LEVELS. The correct volume in a glass measure is obtained by observing the bottom of the meniscus curve horizontally against the scale.

meniscus of liquid—i.e., the lowest level of liquid in the middle of the measure. The measure must be held level and the scale read with the eye at the same level as the liquid surface. With opaque measures the bottom of the meniscus may have to be estimated.

Solid Measures. Powdered chemicals can also be measured out in glass or plastic measures if the volume of a given weight of powder is first found by trial. Once established, the relationship between volume and weight will hold only for that particular chemical in that form. For instance acid fixing powder will need a different measure from hypo crystals.

CC-BY. Wellcome Digital Preservation Foundation, Chandigarh

Solid measures of this type are available for various chemicals (e.g., fixing salt) which need not be weighed too accurately and can be made from old wide-mouthed bottles by affixing a suitable calibration mark (e.g., a strip of gummed paper) at a level corresponding to, say, 1 or 2 ounces. Sometimes the lids of tins in which chemicals are packed are made to hold a specified amount of the contents.

MEDICAL PHOTOGRAPHY

Medical photography is essentially factual. Its primary function is to put on permanent record the salient visible features of the case without embellishment, exaggeration, distortion, deliberate obliteration of detail or recourse to any artistic or spectacular effects. It embraces the whole field of photography and includes a few methods or techniques which are solely medical. The competent medical photographer must be skilled above the average in all aspects of photographic practice and he must possess a general knowledge of human anatomy, elementary physiology, elementary histology, a general knowledge of the terms used in pathology and bacteriology, a general knowledge of medical and surgical terms and their significance, a knowledge of the common processes of treatment, and experience in hospital etiquette.

The apparatus must be the best of its kind and comprehensive because no one type can be expected to cope with all classes of medical photography.

Medical photographs are useless unless they are properly classified and recorded in detail. All data concerning the type of case, the exact methods used to take the negative, and how it was subsequently printed, must be noted and filed. Proper keeping of records is an essential part of medical photographic practice. T.A.L.

History. The first application of photography to medicine was made within six months of the publication of the daguerreotype process, by Alfred Donné of Paris, who made photomicrographs of sections of bones and teeth, February 1840. The earliest publication with engravings copied from photographs of medical specimens is the Atlas accompanying Donné's *Cours de Microscopie* (1845). After the introduction of the wet collodion process, books on photomicrography, including medical subjects, were published by Lionel S. Beale (1857), J. W. Draper (1858) and Josef Gerlach (1863). By the time Albert Londe published *La Photographie Moderne* (1888), with a chapter on medical photography, fast gelatine dry plates and achromatic microscope lenses and condensers had eased the task of the photomicrographist.

The first known use of photography for comparative medical records occurred in 1852. H. W. Berend had photographs taken of his orthopaedic cases in Berlin before and after treatment: the same year Hugh Welch Diamond began photographing mental patients at the Surrey County Asylum. In France, Dr. Baillarger photographed cretins in 1851.

In 1861 J. Ganz started taking stereoscopic photographs for T. Billroth at the Chirurgical Clinic in Zürich, and some were published in 1867. Five years previously the earliest medical publications illustrated with photographs from life had appeared: *Album de Photographies Pathologiques* and *Mécanisme de la Physionogie Humaine*, both by G. B. Duchenne, the founder of electrotherapy, who photographed his patients from 1856 onward.

A. B. Squire, a London surgeon, published hand-coloured photographs of the main types of skin diseases, 1864–66, and A. Hardy in Paris published a dermatological iconography with photographs by A. de Montméja in 1868. For this kind of work the over-sensitivity to blue and violet of the early colour-blind plates had the advantage of exaggerating the texture and discoloration of the skin.

Thousands of photographs of wounds inflicted during the Civil War 1861–65 are preserved at the National Library of Medicine, Washington. *The Photographic Review of Medicine and Surgery*, started by F. F. Maury and L. A. Duhring in 1870 in Philadelphia, was the first medical journal illustrated with actual photographs.

From 1882 onwards great progress was made in medical photography by Albert Londe at the Hospice de la Salpêtrière for nervous diseases. Unco-operative patients were photographed with a small reflex camera worn on a strap round the neck, with which the photographer approached them unobtrusively. This camera is described in Londe's book *La Photographie Medicale* (1893), the earliest specialized treatise on this subject. In post-mortem photography the affected organs were taken with the camera fixed vertically over a table, and the lens stopped down to obtain greatest depth of field. Londe used chronophotography to analyse the movements of epileptics and cripples with a 12-lens

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

apparatus and electrically operated shutters. The twelve photographs were taken on one plate.

Specialized techniques were devised for endoscopic photography. The first good photographs of the larynx were taken by J. N. Germak in 1862 and still better ones were published by Lennox Browne in 1883. He used a 10,000 candle-power carbon arc lamp, with reflector, as illuminant, the light being concentrated through two series of plano-convex lenses, with a plane mirror to reflect the light into the larynx.

The exposure was ¼ second. In 1885 the living human retina was successfully photographed by William Thomas Jackman and J. D. Webster.

Walter Woodbury described and illustrated the Photogastroscope in 1890, but the first practical gastroscopic camera was constructed by the German doctors Lange and Meltzing in 1898. The 2 in. long camera, containing a film 1/5th ins. wide and 20 ins. long, was supplied with light by a small electric lamp. The first photographs of the interior of the bladder were published by Max Nitze, inventor of the first satisfactory photographic cystoscope, in 1894. The following year the discovery of X-rays by Prof. W. C. Röntgen and the introduction of the Lumiére brothers' cinematograph apparatus opened new fields in medical illustration. A.G.

General Photography. Although the very sick or seriously injured patient may be under the direct care of the medical or nursing staff, while the case is in the medical photographic department the photographer is in some measure responsible. He must possess sufficient knowledge of the medical aspects of the case to appreciate the limitations imposed in handling it. He is not normally expected to remove or replace splints or dressings but must be capable of doing so should the need arise, and also be competent to deal with an emergency until medical aid arrives.

General record photographs are standardized in scale of reproduction, angle of view, lighting direction and contrast, and colour rendering. Where the contours are to be shown, photographs are taken from at least two different directions, usually at right angles. Surface lesions are generally photographed first from far enough away to show the lesion in relation to adjacent anatomical landmarks, and then close up to show detail.

STANDARDIZING LAMP POSITIONS. The template fixes the angle and distance from the camera of the lamp. It is easily made from a sheet of cardboard.

General record photography demands not only familiarity with all types of camera and lighting unit, but also the ability to produce comparable standard views of the same and similar cases with different apparatus and not always in the same place or under exactly the same conditions.

Materials. Black-and-white photography still holds pride of place in medical work, but an increasing proportion of photographs are now made in colour. Medium-speed orthochromatic films are most generally useful, with recourse to panchromatic materials where heavy areas of red preponderate (e.g. fresh specimens, operation fields, etc.). In colour photography, 35 mm. reversal transparencies have found the greatest favour. Since each exposure yields but a single original it is wise to make paired exposures so that one can be retained in much the same way that a negative is normally kept. It seems likely that the use of colour negative material for all classes of work will eventually be adopted.

Infra-red. Infra-red radiation is capable of deeper penetration into human tissue than white light; moreover, it is reflected back rather diffusely. If there is some structure immediately below the skin surface which has a higher absorbing property than the surrounding tissue it is recorded on the infra-red photograph as a shadow. For example, the superficial blood vessels appear as a dark pattern against a pale background. For this reason infra-red photography of the superficial venous system can be helpful in examining changes due to varicose conditions, obstruction, heart disease, and pregnancy.

In dermatology infra-red can reveal changes taking place under a superficial scab. In ophthalmic work it has a particular value in enabling photographs of the pupil of the eye to be taken through a cornea opaque to visible light. It may also be used to measure the way the diameter of the pupil changes in response to various levels of illumination since it has no apparent effect on pupillary diameter.

For gross specimens infra-red has been found useful in showing up deposits or tumour tissues not normally differentiated by ordinary photography. To this end specimens may also be injected with special substances which reflect or absorb infra-red radiations, thus introducing differentiation from a photographic standpoint.

The camera and light sources commonly in use in the medical photographic department are suitable for infra-red work in conjunction with the appropriate filters and sensitized material. The almost opaque filters used to filter off unwanted visible rays may be used over the camera lens or the sources of radiation, depending on the type of work being

undertaken. As there will be a difference between the visible and infra-red focus of any camera lens, it is advisable to achieve a preliminary focus through a deep red filter, before the infra-red filter is placed in position.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Stereoscopic Work. Three-dimensional photographs are always useful for indicating depth, especially when views at right angles are impracticable. Cameras with twin lenses are not commonly found in the equipment of the medical photographic department so the photographer must often improvise. This means that he must fully understand the principles of stereoscopy and be capable of adapting his standard apparatus. He must also be familiar with the methods of presenting and viewing stereoscopic pairs.

The medical photographer is usually expected to understand the fundamentals of stereoscopic radiography and the operation of the Wheatstone and binocular stereoscopes for viewing radiographs.

Cinematography. Nowadays considerable use is made in hospitals of cinematograph films—usually 16 mm.—of operating techniques and other suitable subjects. The medical photographer needs to understand the principles of cinematography and be familiar with the handling of up-to-date 16 mm. cinematograph cameras and accessories. He should have experience with black-and-white and colour materials in a studio, in daylight, and under the special conditions of lighting in the operating theatre. He also needs a practical knowledge of script preparation, continuity, camera angles, movements, cutting, animation, titling and editing. It is an advantage for him to be acquainted with special applications like cinemicrography, time lapse and high speed work, as well as sound recording and reproduction.

Dermatology. Skin photographs are used to demonstrate such conditions as inflammatory changes, ulcerations, eruptions and burns. It is usual to take general views to show the location of the lesion and close-ups to show its details.

When a series is taken, standardization of technique is most important. If the purpose of the photographs is to evaluate a change in the colour of the skin, they are made on panchromatic material with correction filters, or colour material with a control of normal skin taken under the same conditions of lighting and exposure. On the other hand, greater contrast may be deliberately produced by using orthochromatic materials or panchromatic plates and films with contrast filters, or the skin texture may be accentuated by employing harsh oblique illumination. Subcutaneous conditions can sometimes be demonstrated by infra-red technique.

Ophthalmology. The external eye can be photographed to demonstrate injury, disease and loss of muscular function. It is desirable to have an apparatus for fixing the head. A small view camera mounted on an ophthalmoscope stand is very useful. Unobtrusive a camera with visual focusing is generally to be preferred—e.g., a miniature reflex.

Special apparatus is used for macrographic study of the iris and vascular network. Part of the internal surface of the eye (the retina) may be photographed through the dilated pupil. The instrument used for this purpose is a combined ophthalmoscope and camera.

Black-and-white, infra-red and colour materials are all used in eye photography.

Dental Photography. Dental photography may be used for general teaching, or for compiling records of unusual and rare conditions, or for making a graphic record of progress during treatment, or for psychological value—i.e., to prove that a particular treatment is having the desired effect. Photographs taken in comparative youth provide a useful guide when contours are to be built up with dentures in later life.

Although most cameras are suitable for this work, it is found best to have a specially designed small and compact camera unit and a simple illuminating system permanently fixed on a bracket table at the chairside. The medical photographer may only be asked to provide technical assistance, exposures being made by the dental surgeon as the need arises. Since colour changes are so important a factor in dealing with teeth and gums, colour materials are definitely to be preferred to black-and-white.

Orthopaedics. The principal use of photography in orthopaedics is to supplement written descriptions. It also provides a permanent record of progress and, where the improvement is gradual and prolonged, it is a means of encouragement to the patient.

Deformities, either congenital or acquired, are photographed with supplementary views to show limitation of function. The details of joint movement generally and the demonstration of gaits are subjects for cinematography.

Plastic Surgery. The value of photography in plastic surgery cannot be over-estimated. Not only are routine records required to show the

MULTIPLE EXPOSURE TECHNIQUE. Two or more exposures on the same negative may show the limits of a body movement for comparison with normal range of movement. This is useful for illustrating progress after injuries or operations.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

protracted stages of almost any plastic repair, but such records may be called upon in the event of litigation. These photographs also play an important part in maintaining the morale of patients who often become discouraged during a long series of operations with little result to see in the intervening phases.

Because so many views are generally required, the miniature camera is often chosen for this work. This approach demands exacting darkroom work to obtain the necessary quality. On the other hand, it makes for portability and interchangeability of equipment to be used in the studio, the operating theatre and the consulting room.

General Surgery. Work in the operating theatre requires not only high technical photographic skill but patience, ingenuity, and ability to work in a team. Knowledge of surgical routine is an advantage as much time is saved if the photographer knows at which stages he is required to take pictures and can be prepared accordingly. The photographer who works in the operating theatre must understand and carry out the rules of asepsis. He must also take precautions against explosions of anaesthetic vapours arising out of electric sparks from his lamps or switches.

Broadly speaking, photographic work in the operating theatre is divided into still, endoscopic, and motion picture. Still pictures mainly show results whilst motion pictures show how the job is done; both may be made at the same operation.

Still photography includes pre-incision views, the operative field at various stages, demonstration of special features, and the final result. There is a difference of opinion regarding the most suitable type of camera, but the choice usually rests between the miniature which can be carried easily into position, as required, and gives a surgeon's eye view, or the larger camera on a heavy duty stand which is either left permanently in one position or wheeled up as required. Sometimes such a stand has a platform, carrying its own flood-lighting units, which raises the photographer well above the operating table level. Otherwise the choice of illumination is flash bulbs or electronic flash (suitably protected) as these permit the use of small lens apertures and provide desirable focusing tolerance. They also give the high intensity light required by colour processes without the undue heat of tungsten or photoflood lamps. For cinematography, the heat from continuous light sources may constitute a problem. In order to overcome this, there are some designs of lamps which make use of cold mirror reflectors, i.e., surface coatings which reflect light, but transmit heat. An additional heat filter is sometimes placed in the light path.

OPERATING THEATRE CAMERA. The camera is fixed on an upright stand and is adjustable in any position with positive locking once adjusted. The focus is fixed in line with the pointer.

Generally speaking, anything which can be seen by means of an endoscope (the instrument used for internal examination through the body orifices) can be successfully photographed. Broadly there are two varieties of endoscopic examination: where the orifice can be widened to permit direct photography; the illumination is usually directional light from spotlights or focused sources, or the speculum used for dilatation may carry a small illumination source at its distal end. Where the endoscope itself carries an optical system and its own illumination, such as the bronchoscope or cystoscope, with a miniature camera attached to the viewing end. By using a special reflex focusing mechanism the field can be selected without removing the camera. Either black-and-white or colour materials may be used for endoscopic photography.

Ultra-miniature cameras have been devised for introduction into the body. One of these is the stomach camera. Such instruments carry their own light source, also exceedingly small, and may be positioned by X-ray screening.

Motion pictures of surgical operations are made for a number of different purposes:

(1) They may be made for general medical exhibition and will be rather lengthy, showing an operation in detail. Such films may include pre-operative investigation, pre-medication data, anaesthetic technique, and post-operative handling and treatment. This type of film may be made up from shots of several patients, so long as the fact is not apparent.

(2) The film may emphasize some particular aspect, such as the nursing and after care of the case for showing to an audience of students.

(3) The film may be a "short" to demonstrate only one special feature, such as a method of injection or suturing. A collection of such shorts is considered very useful for teaching and individual items are easily replaced or revised.

(4) The film may be made to show a new development in operative technique to an audience of specialists; all normal or generally accepted actions are omitted from this type of film.

Motion pictures may be made in black-and-white or in colour but the tendency today

PHOTOGRAPHING SPECIMENS. Top: *General purpose layout. A, modelling lamp. B, fill-in light. C, specimen supported on glass. D, white background.* Bottom: *Set up for even diffused light. E, white cylinder. The light reaches the subject by reflection from the inside of the cylinder.*

is towards colour, except perhaps for the instructional short. Most films are "silent" with suitably printed captions, but more ambitious productions have a sound track added professionally, or by magnetic striping.

Gross Specimens. The subjects in this class of work may be preserved in jars or be fresh from the operating theatre or post-mortem room (where the photography in fact, is often done). A knowledge of asepsis, antisepsis, and general handling of specimens is required of the photographer dealing with such specimens. The preparation of the specimen and the method of presentation may be directed by the pathologist, but a skilled medical photographer is capable of handling routine specimens unaided.

He must know the effects that various immersion fluids have on colour retention, as it has a bearing on his choice of negative materials, illumination and filters.

For black-and-white work, he may use either orthochromatic or panchromatic stock with contrast filters to accentuate red contrast, or panchromatic material with selective filtration to increase contrast, or to produce maximum detail in one selected colour. He may also use colour material. The background in this work is usually of the shadowless type for black-and-white, and a plain colour for colour work.

When the specimen is in a jar, the photographer often has to exercise a considerable amount of ingenuity in order to show the important features, to control specular reflections, and to eliminate unwanted reflections.

Instruments. For the successful photography of instruments and apparatus a good general knowledge of photography is necessary, but the photographer must also know the function of each article so that it may be depicted lucidly. For example, if the parts are disconnected they must be shown in their correct position for assembly.

Bacteriological Cultures. Cultures may be infective or delicate and in either case will call for knowledge and care in handling lest also they become contaminated with other organisms through exposure to the air. The cultures may be on transparent, translucent or opaque media, in test tubes or in Petri dishes. The photographs may be taken by frontal, front oblique, transmitted, or oblique back lighting, on varieties of black-and-white materials with or without filters, and on colour materials.

Macrophotography. Small specimens of all kinds are photographed by direct camera enlargement up to × 10 or even × 20. The medical photographer must therefore be familiar with apparatus for macrophotography, or be able to adapt standard apparatus for such work. He must understand the use of all the standard types of lighting: incident or transmitted light, diffused or direct, and be familiar with the methods of mounting and presenting specimens.

CLINICAL MACROPHOTOGRAPHY. The subject is arranged on a low table to keep the focusing screen conveniently low. A high-power magnifier serves for examination of the image.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Photomicrography. This is an important field of medical photography although it may not be performed in every photographic department.

The work may be done in the pathological, bacteriological, histological, or any department which normally makes visual examinations with the microscope. On the other hand all photomicrographic work may be centralized in one specialist department doing nothing else.

Generally speaking, the medical photographer is expected to possess a working knowledge of the microscope, including types and uses of different objectives and oculars, and sub-stage condensers. He must be familiar with all the common light sources for black-and-white and colour materials, and must also understand the use of special forms of lighting—e.g., dark ground, polarized, ultra-violet and phase contrast.

The experienced medical photographer has at least an elementary knowledge of staining and mounting and is capable of recognizing good and bad slides, as well as elementary tissues.

Trace Recordings. An increasing number of photographic trace recordings are used in modern diagnostic practice. The principal recording instrument is the electrocardiograph. In this the variations in electric potential brought about by heart action are traced by a spot of light on a moving strip of sensitized paper. The developed record shows the cyclic variations as a black wavy line. This technique reveals many types of heart abnormality.

The photographic aspects of electrocardiography and other trace recordings may fall within the province of the medical photographer. He should therefore have a working knowledge of such recording instruments as the string galvanometer and cathode ray tube instruments, the recording materials and techniques used, and the method of presentation of the recording.

Material for Reproduction. With the increasing use of colour materials the medical photographer is likely to be called upon to make colour prints by one of the recognized systems. Here a general knowledge of the subject is less useful than real proficiency in one method.

In addition to normal enlargements from medical photographs, the medical photographer is generally required to make lantern slides, film strips, transparencies, reproductions from radiographs, and facsimile copies of radiographs. He may also be required to organize microfilming of large numbers of radiographs or hospital records.

Other Aspects. The medical photographer is expected to be familiar with the photographic aspects of radiography (so as to be of help should an emergency arise), document copying by reflex and normal photographic negative methods, reversal processing and all its applications, the special uses of fine grain and physical developers, and tropical processing generally. He must have a knowledge of the principles of design and lighting of a studio and darkroom, and the care and maintenance of the electrical equipment. T.A.L. (P.H.)

MEDICAL RADIOGRAPHY

The diagnostic possibilities of the penetrating power of X-rays in medicine were recognized soon after the discovery of this radiation by W. C. Röntgen in 1895.

In the early days X-rays were mainly used in the examination of the extremities of the human body. With the improvement of X-ray apparatus, of photographic techniques and particularly of the medical knowledge of interpretation, radiology developed rapidly to an important branch of medicine. Whereas the term *medical radiology* covers the whole field of X-ray diagnosis and therapy in theory and practice, the term *medical radiography* comprises chiefly the knowledge and the techniques of obtaining pictures by means of X-rays. Such pictures are called radiographs.

BASIC PRINCIPLES

In the production of a radiograph X-rays are emitted from the focal spot of an X-ray tube. The radiation passes through the object to be radiographed and is absorbed differentially within the various regions of the object. The degree of absorption depends on the atomic composition of the object, on its density and its thickness. The radiation transmitted by the object impinges on the photographic material (X-ray film) behind the object. Processing of the X-ray film yields a radiograph in which the shadow images of the various layers comprising the thickness of the object are superimposed. The radiograph is then inspected on a viewing box for interpretation by the radiologist.

At a very early time of the development of X-ray diagnostic techniques it was realized that certain organs, such as the stomach and colon can be made visible radiographically, despite the small difference of opacity in these organs. This is done by giving the patient a drink of radio-opaque substances, such as liquids containing barium. Later it was shown that by means of injections and oral applications of radio-opaque substances other

RADIOGRAPHIC CYCLE. Top: *The image is formed by exposure of the film to X-rays passing through (and being partially absorbed by) the subject.* Centre: *Development and fixation transforms the latent image into a permanent visible one.* Bottom: *The radiograph is viewed by transmitted light against a light box, usually as a negative.*

organs, such as the gall bladder, kidney and urinary tract can be made visible. The principle of this procedure is to introduce elements of high atomic number into the body which increase its subject contrast.

Geometry of Image Formation. The ideal condition for radiographic image formation would be a point projection where each point of the object is reproduced as such in the plane of the image. Owing to the finite size of the focal spot of an X-ray tube this ideal cannot be attained in practice and penumbra effects impair the definition in radiography. Geometrical sharpness depends on the size of the focal spot and on the focus-object film distances according to the equation:

$$P = \frac{F.A}{B}$$

where P = width of penumbra, F = diameter of focal spot, A = object-film distance and B = focus-object distance. Hence unsharpness increases with increasing focal spot diameter, with decreasing focus-object distance and with increasing object-film distances. All radiographic procedures are aimed at improving the sharpness of the image.

The X-ray Tube. This essentially consists of a highly evacuated glass vessel provided with 2 electrodes, the cathode and the anode. The cathode is the filament heated to incandescence during the operation of the tube, and produces a stream of electrons when a high voltage is applied across the two electrodes. The electrons impinge on a tungsten disc embedded in the anode which is usually made of copper. The impact of electrons on the anode produces X-rays.

The anode disc is inclined against the axis of the X-ray tube in such a way that the geometrically effective focal area is reduced with respect to the effective area bombarded by the electrons. This also reduces the optically effective focal spot area.

The X-ray tube voltages used in medical radiography range from about 40–125 kilovolts. Tubes vary in focal spot size and loading capacities. Rotating anode tubes are frequently used in hospital X-ray departments. By subjecting the anode to 3,000 revolutions per minute the focal spot of the tungsten disc is never bombarded to electrons for more than a fraction of a second, making heat dissipation easier than in stationary anode tubes. Hence a considerably smaller focal spot can be obtained with the same loading as for a stationary tube, leading to improved sharpness.

Materials. In the radiography of extremities (hand, arm, foot and legs) where the utmost sharpness of bone structure is often required, the exposures are usually taken on non-screen X-ray films, (i.e. double-coated films of specially high X-ray sensitivity). These may be supplied in light-tight paper envelopes, so as to avoid the insertion of film into cassettes in the darkroom.

The majority of exposures, such as pelvis, abdomen, chest and often skull radiographs are taken on X-ray films sandwiched between a pair of salt intensifying screens. These are layers of calcium-tungstate or barium lead sulphate coated on a flexible support of cardboard or plastic material. When struck by X-rays these screens emit a bluish fluorescent

RADIOGRAPHIC IMAGE FORMATION. Shadow projection from a focal spot of finite size, always produces a penumbra P. This can be reduced by making the ratio B/A as large as possible. (The distances from the focal spot F to the object C and the film D respectively). The penumbra P is also smaller with a smaller focal spot.

light to which the silver bromide grains of the film are particularly sensitive.

With the application of intensifying screens exposure times can be very much reduced if compared under the same radiation conditions with those required for non-screen films and this is the main reason for their use. On the other hand screens impair definition because of the diffusion of their fluorescent light in all directions.

Potter Bucky Grids. X-rays suffer a considerable amount of a scatter when they pass through the thicker parts of the human body. This scattered radiation can be very troublesome in radiography as it impairs the image quality. The most effective method of reducing scattered radiation is the use of a Potter-Bucky grid or diaphragm which is placed between the object and the film during exposure. The grid consists of a series of thin lead strips placed lengthwise side by side and held together, but separated from one another, e.g., by plastic material or wood. The primary radiation emanating from the focal spot of the X-ray tube passes unhindered between the lead strips, whilst the scattered radiation, being random in direction, is absorbed by the lead strips and thus prevented from reaching the X-ray film. As part of the primary radiation is absorbed by the lead lamella and would thus produce shadows on the film, the Potter-Bucky grid is moved during the exposure. There are also stationary grids available in which the lead strips (or lamella) are made fairly thin and the distances between them are considerably smaller than in the movable grids. Although the stationary type of grid leaves shadows in the radiograph, these are less troublesome, when the radiograph is inspected at a distance of about 2 feet.

Fluoroscopy. In certain radiological investigations the patient's chest or abdomen has to be screened by means of a fluorescent screen and a permanent record is not necessarily made. Screening or fluoroscopy is an aid either to follow peristaltic movements of the stomach or colon, to observe the patient's heart in motion or the behaviour of certain organs whilst the patient or the organ moves. Fluoroscopy is carried out with special screens containing mostly a layer of zinc sulphide activated by cadmium or other substances. The screen is usually covered with a lead glass to reduce the dose of radiation received by the radiologist.

Exposure. The many factors influencing exposure can be summarized as follows:

$$\text{Exposure time} \propto \frac{\text{distance}^2}{\text{mA} \cdot \text{KV}^n} \times \text{F}$$

where mA = milliampere, i.e. tube current, KV = kilovoltage across the X-ray tube, n depends on the range of kilovoltages applied and F is a function of the following factors:

(1) Object factor (thickness, atomic weight and density of the object);
(2) photographic factor (type of film, intensifying screen and processing conditions);
(3) filter factor (inherent filtration, Bucky grid);
(4) apparatus factor (circuit of X-ray unit, wave form, etc.).

The contrast of a radiograph is controlled within certain limits by the kilovoltage across the tube. The lower the kilovoltage used, the higher will be in general the radiographic contrast. A further influence on contrast is given be the inherent contrast of the film material and its developing conditions.

Processing. X-ray films are processed in the developers recommended by the manufacturers, such as metol-hydroquinone or phenidon developers. As there are so many variable factors which influence the final image quality, processing of X-ray films is generally standardized for a given developer with regard to developing time, temperature, and using replenisher solutions'

Larger hospital departments nowadays use semi- or entirely automatic processing units which are capable of handling 100–200 larger sized films per hour including drying.

SPECIAL APPLICATIONS

Medical radiography now covers such a wide field of specialized examination methods that only a few of these can be briefly discussed here.

Stereoradiography. If two consecutive radiographs are made and the X-ray tube is displaced by about 6.5 cm. (the inter-pupillary distance) between the exposures, the resulting radiographs form a stereoscopic pair. When these are viewed on a special viewer (e.g. Wheatstone stereoscope) the various parts of the body appear in three dimensions. The method can be used for the localization of foreign bodies or for the determination of certain displacements within the human body etc.

Planigraphy or Tomography. Where a cavity, for example in the lung or a foreign object is obscured in the ordinary radiograph due to the superimposition of the many layers of the object, the image can be made to stand out clearly by the special technique of planigraphy or tomography. In this method the tube and the film are moved during exposure in opposite directions about a common axis. If this lies in the plane of the cavity or foreign body to be examined, all the layers above and below the selected plane will appear blurred in the radiograph but everything in the selected plane will be relatively sharp. Several exposures are usually made before the plane in question is found.

The distances from the front or rear of the patient with respect to the selected plane can be arrived at by this method.

Miniature mass radiography. For chest examinations of a whole population, photographs of the fluorescent screen image are taken on special 35 mm. or 70 mm. square sized films or on

The Wellcome Trust Digital Preservation Foundation Programme

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

TOMOGRAPHY. The X-ray tube and film are moved in opposite directions about an imaginary common pivot during exposure. Everything in the plane of this pivot will then be sharp, everything else blurred. A, B, C, successive tube positions. A_1, B_1, C_1, successive film positions (shown above each other for greater clarity). D, resultant image.

other formats. Specialized equipment is available for this purpose and some of the apparatus is moved in special mass radiography vans to areas where such examinations are intended.

Dental Radiography. In the radiography of teeth small X-ray tubes with fine focal spots are built into easily controllable X-ray units. The small dental film (an X-ray type film specially wrapped in standardized size) is generally held in place by the patient. Because of the small area of the focal spot and the fact that teeth and jaw lie close to the film, good definition can be obtained.

Image Intensifier. One of the difficulties of fluoroscopy is the relatively low brightness level of the fluorescent image. A solution of this problem was found by the introduction of image intensifiers. In one version of such a device X-rays strike a photo-emitting surface and the electrons from this surface are accelerated upon a luminescent phosphor. In the early time of development of image intensifiers a small fluorescent image was inspected with binocular viewers. The popular size of present intensifier images is 7 and 9 ins. The brightness intensification is at least 1,000 times and this permits a considerable reduction in X-ray dose compared with that used in conventional fluoroscopy. One of the main advantages of the intensifiers is that the radiologist can view the image in a non-darkened room, and that they can be used in conjunction with cine cameras and closed-circuit television systems.

Cine-radiography. X-ray cine films were produced very early in the development of radiology and were used either directly or indirectly. The direct method was relatively little in use, as large film cassettes had to be moved in rapid succession. In the indirect method the fluoroscopic image was photographed by a cine camera. Both methods have been abandoned now, because of the high X-ray doses involved. With the introduction of image intensifiers it is now the intensified image that is filmed. This has revolutionized cineradiography and led to a new diagnostic tool of great importance.

Closed circuit television. Using X-ray television combined with image intensifiers the radiologist can conduct his examination by remote control outside the X-ray room. Hence he is removed from the exposure to radiation and he can discuss the picture with his colleagues and can dictate his findings without alarming the patient. A further advantage is the possibility that a large audience can watch the fluoroscopic examination whilst remote from the examination room. In the search for still lower irradiation doses and greater convenience image storage tubes are being introduced. In these the televised image can be held for up to 10 minutes after the X-ray source has been switched off.

Because of the potential hazards involved when working with X-rays these new methods are an important development as they contribute considerably to the use of lower radiation dose levels in the interest of patient, radiographer and radiologist. R.H.H.

Book: *Longmore's Medical Photography*, by P. Hansell and R. Ollerenshaw (London).

MEDIUM SHOT. Shot in cinema production which covers a limited area of a scene in which mainly localized action takes place. This is usually a section of the whole setting of a sequence. When a medium shot involves people, it usually corresponds to a view taking in a small group or single figures shown in full length.

As a medium shot is the intermediate between a long shot and a close-up, its scope is rather broad and usually considered in relation to long shots and close-ups in the same sequence. Medium shots can be sub-classified into medium long shots—taking in a larger view but not large enough for a long shot proper—and medium close-ups, for example of a half-length figure.

MEES, CHARLES EDWARD KENNETH, 1882–1960. English born photographic chemist and physicist. In 1903 Dr. Kenneth Mees, in collaboration with Samuel E. Sheppard, repeated and amplified Hurter and Driffield's work on sensitometry, their results being published in 1907. In 1908 Dr. Mees joined the English photographic manufacturing firm of Wratten and Wainright, and in 1913 established, at George Eastman's request, the Research Laboratories of Eastman Kodak Ltd. at Rochester, U.S.A. which he directed for over forty years. The establishment of a photographic museum at George Eastman House in 1947 was also due to Mees. Author of *The Theory of the Photographic Process* (1942) and other books.

MEGA-. Prefix signifying one million, e.g. megacycles, megohm. Applied mainly to electrical units.

MEGILP. Dope for increasing the richness of the blacks of a print. Mixture of linseed oil and mastic varnish. Also known as magilp.

MEISENBACH, GEORG, 1841–1912. German engraver and art publisher. Founded (Munich 1873) the first zincographic etching establishment in Germany. Started experiments with half-tone screens in 1879 and introduced commercially half-tone screen Autotypie for book printing in 1882. Opened a branch in London, 1884.

MELAINOTYPE. (From Greek melas = black.) Name generally given to Ambrotypes on the Continent.

See also: *Ambryotype.*

MÉLIÈS, GEORGES, 1861–1938. French conjurer (director of the Théâtre Robert-Houdin, Paris). Bought in 1895 a Bioscope from R. W. Paul, decided to make and sell his own films in 1896 and became one of the most famous early film directors, specializing in trick and fantastic films. He ended as a stall-holder in the Gare Montparnasse. Biography by Bessy and Duca (Paris 1945), including an autobiographical section.

MENISCUS LENS. Simplest lens used in photography. It is a single disc of glass, thicker in the centre than at the edges, and it has one face convex and the other concave.

The meniscus shape reduces spherical aberration somewhat, and a small stop in front or behind still more, while the combination of meniscus shape and small stop keeps astigmatism within tolerable limits. The lens is otherwise uncorrected for any of the aberrations.

Single meniscus lenses are found only in the cheapest of snapshot cameras. These lenses are also used as supplementary lenses to alter the focus of the camera lens.

MERCURIC CHLORIDE. Corrosive sublimate; mercury perchloride. Used in intensifiers.

Formula and molecular weight: $HgCl_2$; 271.

Characteristics: White powder. Strongly poisonous.

Solubility: Slightly soluble in water at room temperature.

MERCURIC IODIDE. Used in intensifiers.

Formula and molecular weight: HgI_2; 454.

Characteristics: Heavy scarlet powder. Strongly poisonous.

Solubility: Insoluble in water, freely soluble in solutions of potassium iodide, sodium sulphite, and sodium thiosulphate.

MERCURY. Mercury played an important part in the invention of the daguerreotype process. Daguerre made his first pictures on iodized silver plates which called for very long exposures. He once left some under-exposed plates that he thought were useless in a chemical cupboard where there was a bowl of mercury. Some weeks later the plates carried visible images. Daguerre concluded that the images had been intensified by the mercury vapour.

Today the photographic uses of mercury are limited to the method of hypersensitizing negative materials by exposure to mercury vapour either before or after exposure. The method is uncertain in its effects, but under suitable circumstances it may double the effective speed of the emulsion.

The vapour given off by a drop or two of mercury accidentally spilt in the darkroom can create a puzzling and persistent nuisance. It will penetrate most forms of packing and can completely change the characteristics of any sensitized materials stored in the room. Once it has contaminated a porous surface it is almost impossible to get rid of it.

Mercury vapour in a workroom can also act as a long-term poison so the liquid should be handled with extreme caution and kept in a well stoppered bottle.

One of the principal uses for mercury is as the indicating liquid in thermometers, but mercury thermometers are not easy to read under the darkroom safelight. In thermometers intended for use in photography, the mercury is nowadays replaced by a blue indicating liquid (generally dyed alcohol) which looks black by red or amber safelight illumination.

Many types of mirror are produced by coating a mercury amalgam on to glass or metal, but here also mercury is losing favour. In photography its place is being taken by amalgams of harder metals—particularly for surface-silvered mirrors.

A pool of mercury was used as the backing of the emulsion in the Lippmann colour process for colour images by diffraction.

Another unusual photographic application of mercury is in the so-called photography of perfumes. A speck of the odiferous substance is floated on the surface of a vessel of mercury. After a time, a photograph taken in brilliant cross lighting reveals patterns on the polished surface. These patterns vary according to the nature of the substance and they are only present when it has a recognizable perfume.

Mercury vapour is also used as the luminous gas in certain discharge lamps.

Formula and atomic weight: Hg. 201.

Characteristics: Heavy light grey metal, liquid at normal temperatures. Solidifies at −38° F. (−39° C.). Boiling point 670° F. (357° C.).

MERCURY PERCHLORIDE. Chemical used in intensifiers; mercuric chloride. It is very poisonous.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MERCURY VAPOUR LAMP. Special type of arc lamp in which the glowing arc is maintained in an evacuated glass tube containing vaporized mercury.

See also: *Discharge lamp.*

MERITOL. Proprietary developing agent.

Formula and molecular weight: $C_6H_4(OH)_2$. $C_6H_4(NH_2)_2$; 218.

Characteristics: White crystalline powder.

Solubility: Fairly soluble in water at room temperature.

MESSTER, OSKAR, 1866–1943. German pioneer of cinematography, 1896, the motion picture film industry, and of aerial photography. Designed apparatus and accessories for cinematograph cameras and projectors, and for aerial photography. Donated his collection on the history of motion pictures to the Deutsches Museum in Munich. Autobiography (Berlin, 1936).

METALLOGRAPHY

Metallurgists study the structure of metals with the aid of an optical or electro nmicroscope and frequently use a camera in conjunction with it to record their observations.

SPECIMEN PREPARATION

The metal specimen must, first be prepared in such a way as to reveal clearly the details to be recorded.

Preparation of the Surface. A specimen of suitable size for examination is cut from the object in question taking care not to strain it in the process, otherwise structures may be developed which are related to the strain and not to the original structure of the metal. The specimen is then polished and etched or treated by electrolytic polishing and etching.

The specimen is usually filed, or ground flat on a wheel, before being rubbed down on emery papers of increasing fineness. It is usual to rub down the surface in such a way that the previous lines of scratches are removed by the succeeding scratches of the next finer polishing process—i.e., by working in a direction at right angles to the existing scratches. In this way the effects of the previous scratches can be completely removed. It is usual to use emery papers numbers G,.M, F, 0, 00, 000 in succession; the use of papers finer than 000 is generally of little value, and in some cases, particularly for electrolytic polishing, 00 emery paper is sufficiently fine. To remove these last fine scratches, the specimen is then polished on a revolving pad covered with either selvyt cloth, special cloth or velvet, to which the polishing powder is added, the pad being kept moist with running water. This last stage of the polishing process induces the formation of a thin layer of "flowed" metal on the surface, the irregularities of the scratched surface being partly rubbed away and partly filled up.

The powders employed in polishing depend upon the nature of the metal and are usually oxides of aluminium, magnesium and chromium, and in particular cases, diamond dust. For soft metals, such as aluminium, magnesium, zinc, etc., alumina, which is levigated to get a particularly fine particle size, is used. For hard metals, such as steels, chromic oxide is used; and for very hard substances, like tungsten carbide, fine diamond dust.

Etching. After the specimen is polished, the actual structure of the metal is revealed by the process of etching. This consists of dipping the specimen in an alkaline or acid solution for a few seconds or more, thereby allowing an attack on the surface to take place, which first removes any film of flowed metal; the attack is of a chemical nature. If the metal is homogeneous, then the etching reagent will dissolve

EFFECT OF ETCHING. This dissolves away different solid phases, crystal face or constituents at varying rates, and thus produces hollows or crystal patterns that are characteristic of the parts treated. When vertically illuminated and examined under a microscope, the various surface areas reflect the light in different ways and thus show up structure.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

away the surface of each crystal of which the metal is composed, in amounts depending on their respective orientations. Under vertical illumination the junctions of these crystal faces will appear dark, since the surfaces of adjacent crystals have been differently attacked. But if the specimen is not homogeneous and contains one or more constituents or phases, then an etching reagent is chosen which will attack one or other of the constituents so that it can be identified in the presence of others by its difference in colour. The exact choice of etching reagent depends upon its chemical relationship with the metal or alloy.

Electrolytic Polishing. Instead of the above standard methods of polishing and etching, electrolytic polishing offers a particular advantage when a metal is soft and therefore not easy to polish. The specimen is prepared as before down to 00 emery paper and then is made the anode in a suitable electrolyte so that the surface of the specimen is removed by the passage of the current. Electrolytic etching may be carried out in the same bath, but using a lower voltage.

Thin films suitable for transmission electron microscopy are prepared in the same way from material which has already been thinned down to 200 microns or less. The final thickness necessary for adequate electron transmission must not be more than 1000A (0.1 micron).

Vacuum Evaporation. Thin films may also be formed by deposition of the metal on to a suitable substrate, but this method does not give specimens which are representative of the bulk material. The most common deposition method is that of thermal evaporation in a vacuum. The metal to be evaporated is usually placed in a basket or boat of molybdenum or tungsten, or if in the form of a thin wire, is wound round a tungsten filament. Under high vacuum, a heavy current (20 amperes or more) passed through the basket or filament causes the metal to melt and finally evaporate. It is collected on a substrate of suitable material from which, if required, it can be removed at a later stage. The two most common substrates used are mica and rock salt (sodium chloride).

Sectioning. Thin specimens may also be obtained by cutting with a microtome from bulk material, but this method invariably introduces strain, and is not suitable if the specimen is required for deformation or dislocation studies.

Replication and Shadowing. A method of wide application in transmission electron microscopy which overcomes the disadvantage of thick opaque specimens is that of replication. Briefly, it consists of coating the specimen with a material such as formvar or evaporated carbon, so that the latter takes up the surface topography of the specimen. The replica is then removed, either by stripping or by destruction of the specimen.

The visibility of surface details can be improved by shadowing. This is the deposition of a thin film of metal obliquely on to the object by evaporation in vacuo. Regions of the specimen screened by projections show up as areas of higher electron transmission so that heights and depths of projections and depressions respectively can be evaluated from a knowledge of the angle of deposition.

Metals widely used for shadowing are gold, palladium or an alloy of the two. A carbon/platinum mixture gives a deposit almost free of structure.

RECORDING METHODS

Photomicrography. A photographic record of what can be seen under the microscope is of immense value in the study of metals. Different ways of illuminating the specimen have resulted in the development of new techniques for further elucidating metal structures. Permanent records of the appearance of the specimen can then be carried out by a suitably modified technique of photomicrography. There are a number of such techniques in normal use.

(1) Vertical illumination: in the examination of opaque bodies, such as metals, a device known as the vertical illuminator is generally used. This consists of a plane glass reflector mounted immediately behind (above) the objective and reflecting light on to the specimen. The light passes by reflection from the specimen, back through the vertical illuminator to form the final image. The source of light is often a small electric bulb with a very finely-ground glass diffusing screen between it and the glass reflector. If the source of light is so placed that its distance and that of the focal plane of the eyepiece from the reflector are equal, then "critical illumination" is obtained. This is the best mode of illumination possible.

Both achromatic and apochromatic objectives can be used. When work of a really critical nature is undertaken—e.g., as in high-power photomicrography—apochromatic objectives are best; but for routine observations, the less expensive achromatic objectives, if of good quality, are quite satisfactory. When apochromatic lenses are used, the red, green and blue rays are united at the same focus, thus eliminating the secondary spectrum and producing an image free from colour interference. Achromatic objectives are not free from secondary spectrum.

For metallographic work, the most useful objectives are 25, 16, 8, 4 and 2 mm. (uncorrected for cover glass). The 2 mm. objective is an oil immersion lens with a numerical aperture (N.A.) of about 1·4. In order to get the best results from any objective, the magnification of the image should not exceed 1,000 × N.A. For convenience a chart can be constructed relating camera extension to magnification for each objective.

Since the resolving power of an objective is directly proportional to its N.A. and inversely proportional to the wavelength of light used

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

VERTICAL ILLUMINATOR. L. small light source. R, plane glass reflector. S, subject. a, distance from lamp to reflector. b. Distance from reflector to focal plane of eyepiece. The light from the lamp is reflected on to the subject. and reflected back through the illuminator into the eyepiece. For critical illumination the lamp distance from the reflector should equal the distance of the reflector from the focal plane of the eyepiece; the subject then appears at its brightest.

(i.e., it varies as N.A./λ) it follows that the larger the N.A., the greater the resolution or the finer the structure seen; the shorter the wavelength the greater the resolution. Hence it is usual in photomicrography to use filters passing wavelengths from 400 to 600 mμ in conjunction with backed process plates (blue-sensitive) or orthochromatic plates (blue- and green-sensitive).

(2) Oblique (dark ground) illumination: in certain circumstances structures may be more clearly revealed if the light falls obliquely on to the metallic surface before entering the objective. Special objectives are made with annular mirrors built into them, so that the external source of light falling on the mirror is reflected on to the metal surface and then back through the objective to the eyepiece.

(3) Polarized light: structural features can be observed on polished metallic specimens under polarized light which are not discernible under vertical or oblique illumination or by the aid of phase-contrast microscopy—e.g., a ray of polarized light may be unaffected by the metal itself, but de-polarized by impurities which would therefore appear dark. An ordinary microscope can be fitted with the necessary polarizing devices.

(4) Phase-contrast microscope: this type of microscope depends on the difference in phase of the light reflected from constituents which lie at different levels at the specimen surface and gives clear distinctions between constituents which are otherwise difficult to distinguish photographically. The alterations required to convert an ordinary microscope into a phase-contrast microscope are simple in principle.

Electron Micrography. The primary advantage of the electron microscope over the optical microscope is its much higher resolving power (about 200 times greater for a modern high resolution instrument), so that much finer details of specimen structure can be recorded. In particular the presence of dislocations can be detected in transmission microscopy of thin films.

Three modes of examination of metals by the electron microscope can be distinguished.

(1) Electron transmission: This is the method most generally employed and is applied to the examination of replicas or thin films. The latter must not exceed 1,000 A in thickness for examination in conventional instruments.

(2) Electron reflection: An image can be formed by collecting electrons scattered from a metal surface on which an electron beam is incident at a small angle. This reflection method has the advantage that it can be used with bulk metal specimens. The resolution obtainable is low for an electron microscope, but may be as much as 10 times that of the optical microscope using vertical illumination.

(3) Electron diffraction: Electrons are diffracted by a crystal lattice in a manner analogous to X-rays. In modern electron microscopes it is possible to make a simple adjustment of the optical system to enable a diffraction pattern of a small area of a specimen to be imaged on the screen of the microscope or recorded photographically. The crystal structure of the material on which the electrons are incident can be deduced from the pattern, an operation which may serve to identify chemically the area under examination.

Investigations with X-rays. Micrography by X-rays (radiography) permits the investigation of large metallic objects. By this means it is possible to determine the positions of holes, impurities, flaws, etc., in the interior of the metal.

For a more detailed structural examination, microradiography may be employed. This allows the discovery of cracks, microscopic inclusions and crystal shape.

X-ray crystallography provides a means of investigation of the atomic structure of metals.

METAL PRINT. Metal and other solid surfaces can be treated so that they can be printed with a photographic image. The printing may be carried out by contact printing by daylight or artificial light, or by enlarging.

After varnishing to prevent chemical action between the processing solutions and the bare metal, a photograph can be applied to it by any of the following methods:

(1) The surface may be brushed over with a sensitized coating or emulsion, exposed under the negative by contact or in the enlarger, and then developed.

(2) It may have the image transferred to it by the method of transfer coating.

(3) It may take the place of the final support in the carbon or carbro processes.

See also: *Printing on special supports; Stripping.*

METER. Instrument with a moving pointer, counter or scale used for measuring. In photography, special meters may be used for determining the strength of the light when making exposures in the camera (exposure meter) and printing from the negative (generally a photometer); for measuring the colour temperature of artificial light sources (colour temperature meter); for measuring distances (telemeter—i.e., rangefinder); for measuring the temperature of solutions (thermometer); and for measuring the current and voltage in electrical equipment (ammeter, voltmeter).

Also U.S. spelling for metre.

METHYL ALCOHOL. Wood spirit. Simplest alcohol. In the commercially pure state it may be used as a substitute for ordinary alcohol—e.g., for rapid drying of negatives.

Formula and molecular weight: CH_3OH; 34.

Characteristics: Volatile clear liquid. Poisonous.

Solubility: Miscible with water, ethyl alcohol acetone, and most other solvents in all proportions.

METHYLATED SPIRIT. Commercial form of alcohol, denatured by various additions to render it undrinkable (pyridine, various oils), and usually dyed purple to draw attention to its denatured state.

METOL. Elon; Genol; Photol; Pictol; Planetol; Rhodol; monomethyl para-aminophenol sulphate; para-hydroxy-monomethylaniline sulphate; 1-hydroxy-4-methylamino benzene sulphate. Developing agent.

Formula and molecular weight: $(CH_3NHC_6H_4OH)_2.H_2SO_4$; 344.

Characteristics: White crystalline powder. It may cause skin poisoning with some people allergic to it.

Solubility: Fairly soluble in water at room temperature. Less soluble in sulphite and alkali solutions.

METOL-HYDROQUINONE (MQ) DEVELOPER. Very common class of photographic developers based on a mixture of the agents metol and hydroquinone. A mixture of these two agents has advantages which, for many uses, greatly exceed those of the separate constituents. The proportions of each, and the amounts of the other constituents of the developer, vary according to the material to be developed—e.g., plates, films, or papers—and the effect aimed at—e.g., soft or contrasty image.

METOQUINONE. Developing agent containing a combination of metol and hydroquinone. On dissolving, the two developing agents are liberated.

METRE (METER). Unit of length in the metric system. Originally (1801) specified as one-ten-millionth of a quarter of the earth's circumference (equator-to-pole distance). The reference standard is now the distance at a standard temperature between two marks engraved on a platinum bar preserved in Paris.

See also: *Weights and measures.*

METRE CANDLE. Unit of illumination more usually known as the candle metre and also as the lux.

See also: *Light units.*

METRIC SYSTEM. System of weights and measures laid down in 1801 by the French Republic and now almost universally employed for scientific measurements on account of its arithmetical convenience, as all units are interrelated in terms of 10 or its powers.

The basic unit is the metre, originally specified as one-ten-millionth of the pole-to-equator distance. When this distance was measured more accurately and found not to agree with the original metre, the latter was referred to a standard metal bar preserved in Paris (copies of which were preserved in other national capitals). More recently the metre has been redefined in terms of the wavelength of a specified spectral line.

Length in the metric system is measured in kilometres (1,000 metres), metres, centimetres (1/100 of a metre) and millimetres (1/1000 of a metre).

Area is measured in squares of the above units and also in units of 1 hectare (10,000 square metres) and 1 are (100 square metres).

Volume is measured in cubic centimetres (c.cm.) and multiples and sub-multiples of the litre (the volume of 1 kilogram of pure water at 4° C.).

Millilitres and cubic centimetres are virtually (though not absolutely, due to a slight difference in definition) identical in size.

Weight is measured in terms of the gram

(originally specified as the weight of one cubic centimetre of water at 4° C. but now referring to a standard weight preserved in Paris). Other units are the milligram (1/1000 gram) and kilogram (1,000 grams).

An Act of Parliament, passed in 1864, made the system legal in Great Britain. The inch equals 2.54 cms.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Imperial weights and measures are now defined by reference to the metric standards.

See also: *Weights and measures.*

MICRO. Prefix indicating one millionth part of any unit. Also used as a prefix to indicate anything small or minute or used for examination or measurement of small objects.

MICRO-COPYING

Method of photographing original documents, drawings, etc. at a greatly reduced scale on film or paper. Being considerably less bulky, such micro-copies save valuable storage space. When required they can be read by optical apparatus or printed on sensitized material to produce a copy of the size required. Micro-copying methods, usually on film, serve many purposes, but were originally intended to preserve in reduced form valuable documents against their loss by fire or other causes. They can also be used for other security and preservation purposes, because micro-film, correctly processed and stored, will outlast all the normal types of paper.

In 1853 Sir John Herschel suggested copying reference works, public records etc., on microscopically small negatives and using an enlarger to reproduce them on a readable scale. His proposal had to wait 85 years for realization, for microfilm documentation was only begun on a large scale under the threat of war about 1938, when the most valuable books in the British Museum were copied on 35 mm. film, and some newspapers had microfilm copies made of their old volumes. Banks also began adopting the system for their records.

Any number of duplicates of the original microfilm can of course be made and, thanks to this process, copies of rare books and records have been made available to students and libraries all over the world. It may well be that the libraries of the future will consist of collections of microfilm copies of books, manuscripts and newspapers, occupying something like one hundredth or less of the space and capable of yielding further copies at quite a small cost compared with other means of reprinting or reproduction.

The airgraph service used during the last war is an interesting application of micro-copying. A form upon which a message of some 700 words could be written by the sender was copied on microfilm, sent overseas, and then reproduced photographically at its destination for a cost of less than one penny per letter.

The main kinds of micro-copy in current use are continuous roll microfilm, unitized film cards, and micro cards.

Microfilming. The straightforward system of micro-copying of documents, etc. is to photograph them one by one on a roll of 16 or 35 mm. film. The 16 mm. gauge is more compact from the point of view of convenience in storing, but 35 mm. film may be necessary where very large originals are to be copied (for example plans and drawings). To preserve the maximum amount of detail in big engineering drawings, 70 mm. or even 105 mm. wide film is sometimes used.

MICROFILM SIZES. A, 35 mm. film. This can be used either perforated or unperforated. Perforated film provides a choice of full frame 24 × 36 mm., half-frame 18 × 24 mm. or smaller split sizes. The standard image area on unperforated film is 32 × 45 mm. used for drawing offices. B, 16 mm. film at a 1 : 19 reduction, for documents, correspondence, etc. C, 16 mm. microfilm used at 1 : 40 reduction, providing four times as great a capacity per film length. The 16 mm. sizes are both unperforated.

A form upon which a message of some 700 words could be written by the sender was copied on microfilm, sent overseas, and then reproduced photographically at its destination for a cost of less than one penny per letter.

The main kinds of micro-copy in current use are continuous roll microfilm, unitized film cards, and micro cards.

Microfilming. The straightforward system of micro-copying of documents, etc. is to photograph them one by one on a roll of 16 or 35 mm. film. The 16 mm. gauge is more compact from the point of view of convenience in storing, but 35 mm. film may be necessary where very large originals are to be copied (for example plans and drawings). To preserve the maximum amount of detail in big engineering drawings, 70 mm. or even 105 mm. wide film is sometimes used.

MICROFILM SIZES. A, 35 mm. film. This can be used either perforated or unperforated. Perforated film provides a choice of full frame 24 × 36 mm., half-frame 18 × 24 mm. or smaller split sizes. The standard image area on unperforated film is 32 × 45 mm. used for drawing offices. B, 16 mm. film at a 1 : 19 reduction, for documents, correspondence, etc. C, 16 mm. microfilm used at 1 : 40 reduction, providing four times as great a capacity per film length. The 16 mm. sizes are both unperforated.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Continuous microfilm is the most suitable method for micro-copying great volumes of coherent material, such as books, complete files of correspondence, etc. The reduction ratios employed vary from about 1 : 10 (on 35 mm. film) to 1 : 40 (16 mm.).

For locating individual items on a continuous roll of microfilm (usually up to 100 feet of film length) a separate indexing system is usually necessary. This specifies the roll on which any item is recorded, and the position of the required information on that roll. Special film readers reel the film through at high speed, while suitable locating marks between the frames enable the position of any one to be determined with reasonable accuracy.

Unitized Film Cards. Where a roll of microfilm covers a large number of disconnected items, keeping track of them requires an indexing system appreciably larger in bulk than the microfilm record. It then becomes more practical to file individual microfilm frames or groups of frames (short strips) as separate units.

The current means of such unitized treatment is the film card: an index card 3 × 5 ins., 3¼ × 7½ ins. (tabulator card format) or in one of several other reasonably standard sizes. The card carries a cut out aperture in which the microfilm frame or strip is located. The film may be held in the aperture either by a transparent and very thin plastic envelope, or by transparent adhesive tape. The mounting procedure is usually mechanized and there are various machines which cut the individual frames from the continuous microfilm roll and automatically place them in the aperture card at the rate of some hundreds or even thousands an hour. This is important in organizations using film cards in bulk, to avoid the mounting operation from becoming a handling bottleneck.

The microfilm cards can then be filed in any group or subject filing system. An alternative method is to use tabulating punched cards as aperture cards, retrieving any individual microfilm image by high speed mechanical sorting systems.

Microfilm Sheet and Micro-cards Sheet film is also used for microcopying, partly to avoid the inconvenience of using film in roll form for such purposes as the publication of out of print books and periodicals, and partly for copying very large and often poor originals. For publication purposes sheet film is used in a camera of the step-and-repeat type, which holds a flat sheet of film on which small images are recorded in rows. The number of images is determined by the reduction ratio used, about 80 being average although much higher recordings have been made.

The negative obtained in this way can be printed on to a sheet of transparent film to produce a positive, or on to opaque card 3 × 5 ins. These are micro cards. Similar opaque cards exist in many forms. One type for instance contains 100 images on a 6 × 9-inch card and is printed by lithography from 35 mm. film. Another kind, made especially for the legal profession, contains 200 images on each side of a card 6½ × 8½ ins.

Micro-positives can also be made on an opaque strip of sensitized material, printed from a negative roll. The opaque strip or tape has an adhesive backing which permits it to be cut in any required length and attached to any card, additions being made as required.

Micro-cards of this kind are useful as they allow direct filing of appreciable amounts of information on a single card. Also, since any number of positive micro-copies can be made, cross filing and multiple filing is greatly simplified. This method is cumulative, so that any number of new items can be added as required.

Such a system is thus a halfway house between roll microfilm and unitized single frame filing. (But some types of unitized aperture cards will also take up to a dozen microfilm negative images in strips.)

An important variant of microfilming is the recording on microfilm both of text and of a binary code. This code is used to search electronically at extremely high speeds, and—with some apparatus—to produce a readable copy automatically from the film. For certain applications it is even more convenient to encode the whole information on the microfilm in a binary system.

Equipment. Microcopying is carried out by various forms of special miniature camera equipment with film magazines to carry several hundred feet of film. The camera is generally mounted above a table with a flexible system of lighting so that a range of sizes of document can be evenly illuminated. In advanced apparatus, the setting and release of the shutter, the control of the lighting, and even the turning of the pages of the book are synchronized and remote controlled.

Many normal miniature cameras also can be adapted for microcopying with specially designed accessories for this purpose.

The cameras used for roll microfilming on a large scale are generally of two types, planetary and continuous. Planetary cameras record a set number of images, usually 1,600, 800 or 600 on a roll of 100 feet. The camera moves along an upright column to give varying sizes of reductions, so that two or more small pages can be photographed simultaneously. This type of apparatus is normally suitable for single sheets, large or small, books and magazines. After every exposure, the film is automatically advanced to a new frame. The documents must, however, be moved manually.

The continuous type of camera is normally limited to single sheets, about 12 ins. wide, but these can be of any reasonable length. They can be fed into the camera by hand, or mechanically at very high speeds. The exposing unit automatically illuminates and photographically

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MICRO-FILMING CAMERA. A, camera unit. B, fixed lamps. C, exposure meter on movable arm to swing over document to be copied, and providing standard exposure times for all originals after calibration. D, exposure control wheel, acts by varying the light intensity. E, foot switch operating the shutter. F, reduction scale on column. G, camera control wheel for raising and lowering camera unit, also adjusts lens focus.

records the original, repeating this operation with each document. By this means a variable number of documents can be recorded on the film, the actual number depending on the length of the original and other conditions.

In the most advanced continuous microfilm cameras the film constantly moves past a narrow slit, while the originals are carried on a moving band past the camera below the lens. The movement of the film and of the originals is synchronized, so that the camera continuously records a sharp image on the film. Cameras of this kind can microfilm documents at the rate of several thousand an hour.

Automatic microfilming cameras also exist for producing film cards with the micro-copy ready mounted in an aperture card. The copying unit is here loaded with stacks of aperture cards carrying unexposed microfilm. The cards are moved into the image plane of the camera one by one for the exposure, and then pass through a developing, fixing, washing and drying sequence. The solutions are sprayed on the film surface. After processing and drying, the machine delivers a film card ready for filing. The whole operation is automatic, and the operator only has to place the originals on the copying table and press a button. The output speed is not very high, but this system eliminates the manual work of processing, cutting and mounting the microfilm.

Some cameras can photograph both sides of a double-sided document simultaneously on the same film. The original here is suspended between two mirrors which reflect the image from each side into the lens of the microfilm camera. With more conventional microfilm cameras, recording of two sides of a document involves turning the original over between one exposure and the next, or making a double exposure with the original placed in alternate halves of the copying easel. The latter has to be covered with black non-reflecting material to avoid fogging of the half of the film not being exposed.

Cameras for large size (sheet film) microfilming are often of the horizontal type. They hold the original on a vertical easel, while the camera runs on rails to permit variable reductions. The easel may be illuminated from the front as well as from the rear (through a translucent panel), for copying opaque as well as transparent or translucent originals.

Films and Processing Microfilm used for micro copying must have very fine grain, usually high contrast and high resolving power because the image is naturally very small. Several of the major film manufacturers provide special emulsions for microfilming in 16 and 35 mm. perforated or unperforated form. The unperforated type permits a more efficient utilization of the film size.

70 mm. film for microfilming has similar characteristics, while sheet films, where used, are usually fine grain process emulsions.

Microfilms are generally available both as blue sensitive (non-colour sensitized) and as panchromatic emulsions. The latter are preferable when multi-colour originals have to be copied; non-colour sensitized emulsions are more frequently used for making positive copies.

Microfilms are normally processed to the

FLOW CAMERA. This type of microfilming camera records continuously. The documents are fed into it manually or automatically, move smoothly through the apparatus while being exposed, and return to the operator. The film moves continuously in the camera, in synchronism with the document movement, to keep the image sharp. A, camera, usually taking 100 feet of film at one loading. B, lights. C, document being fed in. D, drive rollers. E, exposure area between rollers. F, return chute.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DUAL MICROFILMING. This serves for simultaneously copying both sides of a document. The front and the back views are reflected by mirrors to the camera, recording both sides side by side on the film. A, camera. B, panel of lamps to illuminate document. C, front mirror. D, document (edge on view). E, drive rollers. F, rear mirror.

highest possible contrast (gamma values of around 2·5 to 4) for easy readability. Softer development may be required if continuous tone or half-tone originals are copied, but it is rarely possible to allow for this with large output cameras, unless such originals are presorted and copied together.

All sizes of roll microfilm can be developed manually, using reels to hold the film. For microfilms made in an ordinary miniature camera (36-exposure cassette loads) an ordinary amateur developing tank is suitable for occasional use, though rather slow. Bulk lengths of 100 feet are normally processed in big reel tanks or in apparatus which continuously winds the film from one reel to another while immersed in the processing solution. Automatic temperature controlled film processing machines are also used in larger establishments.

Sheet film is normally processed manually in tanks.

Duplicating Duplicate microfilm rolls, where required, are produced by contact printing in special printers or by projection printing on apparatus similar to optical motion picture printers.

In addition, microfilm duplicates are frequently produced on diazo film which is processed by simple heat treatment, requiring no liquid application. Equipment is available which produces contact duplicate microfilms either from continuous rolls or from film cards. With some systems duplicate film cards are made on diazo film pre-mounted on aperture cards, and in printing equipment that can produce several hundred duplicates an hour. Such duplicates are required for cross filing and also for distributing, for instance microfilmed engineering drawings, in a number of departments of a manufacturing firm.

Readers and Printers For direct reference to microfilm negatives special viewing apparatus is available. These microfilm readers usually take the form of a table viewer with a back projection screen of 18 ins. square or more. The film, on a spool, is fitted into the viewer and threaded on to a take-up spool in much the same way as in a cine projector. Operation of a control knob or lever moves the film to bring a new frame on to the screen. In addition such viewers may incorporate a rapid film transport to bring a frame from, say, the middle of a reel

MICROFILM READER. This projects the image optically for viewing and sometimes also permits photographic enlargements by direct projection. Left: Mirror in reading position. Right: mirror in enlarging position. A, projection lamp. B, film. C, mirror. D, reading screen. E, paper holder in raised position for small prints.

quickly into position. In advanced units built-in sensing devices can automatically bring any required frame into the picture gate on adjustment of a selector mechanism.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Mostly microfilm viewers enlarge the microfilm image from 12 to 20 times, to bring it back to approximately original size. Viewers for unitized film cards, and also for micro-cards work on similar principles; a micro-card viewer illuminates the card by reflected light.

Combined camera and viewing equipment is also made, so that the apparatus can be used for both copying and viewing. On the other hand microfilm viewers frequently incorporate their own printing system for re-enlarging microfilm frames. The required frame is located on the viewer screen, after which a swinging mirror re-directs the projected beam on to a sensitive paper surface for making the enlargement. Reader printers mostly use electrophotographic, electro-lytic or diazo materials for the re-enlargement, and the positive copy emerges from the printer within a minute or so, ready processed. The largest units can re-enlarge microfilms to the size of big engineering drawings.

Microfilm negatives can also be enlarged on to document copying paper—usually of the fast projection type—for processing in the conventional way (developing, fixing, etc.) or in motorized rapid roller processing units.

Continuous flow electro photographic printers, using the drum principle, exist for re-enlarging microfilms in bulk. The film moves continuously through a projector which projects the enlarged image on to a rotating selenium drum. This is charged, exposed, treated with charged pigment powder, and the image transferred to ordinary paper at various points around the circumference of the drum. The paper enlargements then emerge in a continuous strip or web and such units can produce full size enlargements at a web speed of 20 or more feet per minute.

This particular system has been used in reproducing photographically out-of-print books, rare editions, etc.

Zinc oxide coated paper is also used in electrophotographic printers. Here the paper is charged and image exposed, developed and fused on the paper itself, so that no selenium plate or drum is required. H.W.G., L.A.M. & H.R.V.

Books: *Camera Copying and Reproduction*, by O. R. Croy (London); *Micro-Copying Methods*, by H. R. Verry (London).

MICROFILMING Technique of copying documents etc., on a greatly reduced scale on 16 or 35 mm. (or sometimes wider) film for compact filing and storage. Microfilms may be stored in roll form or as unitized film cards, carrying microfilm frames or strips of frames in pockets or in a cut-out aperture.

The microfilm material used is usually a panchromatic emulsion of very fine grain and high resolving power. In the 16 and 35 mm. gauges it may be perforated or unperforated.

See also: *Micro-copying.*

MICROFLASH. Electronic flash of extremely short duration (of the order of 1/1,000,000 second) used for the photography of specially fast moving subjects—e.g., in ballistics, design of machinery, aircraft research, and others.

See also: *High speed photography.*

MICRON. One millionth of a metre, also sometimes known as micrometre. The term is most commonly used in expressing the wavelength of light.

See also: *Light units.*

MICROPHOTOGRAPH. Photograph made on a greatly reduced scale; the opposite of a photomicrograph. J. B. Dancer produced microphotographs 1/16 in. in diameter, taken on microscope slides, to be viewed in a powerful microscope, May 1853. They became fashionable six years later. Microphotographs were also sometimes set as jewellery under thick plano-convex Stanhope lenses, and in fancy goods such as penholders. In October 1857 Sir David Brewster forecast that microphotographic copies of secret dispatches might be placed in a space no larger than a fullstop, and transmitted by post. During the Russo-Japanese War, 1904–5, it was stated that Japanese spies carried microphotographic reports under their nails, in their nostrils, and in their stomachs in ivory containers that resisted the gastric juices. Present-day microfilming is the modern application of microphotographs which can under special circumstances reduce documents several hundredfold.

MICROPHOTOGRAPHY. Term used on the Continent for the technique of making large photographs of very small objects through the microscope. In Britain and the U.S.A. this technique is known as photomicrography, while the term microphotography is applied to the reverse method—i.e., of making microscopically small photographs of objects by optical reduction.

MICRORADIOGRAPHY. Special radiographic technique for examining the internal structure of thin specimens at high magnifications. The technique is also known as X-ray micrography.

To make a microradiograph, a plane section

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of the specimen up to 1 mm. thick is placed in contact with the emulsion of an ultra-fine grain film or plate and exposed to a source of X-rays.

The image in the emulsion is then enlarged up to 300 times for examination, and shows the internal structure of the specimen.

The technique depends on the use of the finest grained emulsion possible. Before modern ultra-fine grain materials became available, Lippmann emulsions were employed.

MIETHE, ADOLF, 1862–1927. German astrophysicist. From 1899 Professor at the Technische Hochschule (Technical University) in Berlin as successor of H. W. Vogel. Earlier a director of Voigtländer & Söhne. Calculated an aplanat lens in 1888 and introduced a tele objective in 1891. In 1902 discovered new isocyanine sensitizing dyestuffs (with A. Traube); the Aethyl-Rot was used in the panchromatic Perutz Perchromo plates in 1904. Also worked on three-colour additive projection and printing.

MILE. (Lat. mille, a thousand.) Lineal measure equal to 1,760 yards, or 5,280 feet. Originally 1,000 paces or roughly 1,680 yards.

The nautical mile, standardized by the British Admiralty, is approximately one minute of arc of the earth's surface and equals 6,080 feet. This is also the British Geographical mile.

The International Geographical mile is one-fifteenth of a degree of the earth's circumference measured at the equator and equals approximately 4·61 statute miles—i.e., miles of 5,280 feet.

See also: *Weights and measures.*

MILLI-. Prefix signifying a thousandth part of. It is used principally in the metric system—e.g., millimetre, millilitre, milligram.

See also: *Weights and measures.*

MILLIMICRON. Thousandth part of a micron, used principally to measure the wavelength of light rays.

See also: *Light units.*

MINIATURE CAMERA

Term applied generally to camera using perforated (or sometimes unperforated) 35 mm. cine film as negative material for still photography.

A wider view, based on an official definition by the Royal Photographic Society, includes cameras taking negatives up to 2¼ ins. square. However, there are many constructional principles and points of technique which specifically apply to 35 mm. cameras and are not shared by roll film cameras (even for negative sizes below 2¼ ins. square). For that reason the term miniature camera is here used only for cameras taking 35 mm. film.

Precision. Miniature negatives have to be enlarged to yield prints of a reasonable size and this magnifies any shortcomings of definition. So the camera has to be constructed with greater mechanical precision and fitted with lenses of a higher standard of sharpness than a larger camera of comparable quality.

The degree of enlargement necessary also emphasizes grain and physical faults in the negative. The films therefore require much more careful treatment, and often special fine grain processing. From the start, miniature cameras were thus associated with a particular miniature technique of photography. In due course this not only influenced technique with larger film sizes but was also responsible for great advances in film manufacture.

Film. The majority of 35 mm. miniature cameras take 24 × 36 mm. (approx. 1 × 1½ in.) negatives, but some take 24 × 24 mm. negatives, and a few, odd sizes like 24 × 32 mm. The 24 × 32 mm. size is an attempt to get away from the stablished 24 × 36 mm. format.

A second fairly popular size is the 18 × 24 mm. half-frame (i.e. half the full 24 × 36 mm. frame). This reduced picture area permits an appreciable scaling down of the camera size, leading to more compact cameras.

As 35 mm. film has no backing paper, film transport has to be entirely mechanical. The perforations of the film are utilized for this purpose. The transport system therefore usually consists of a sprocket wheel or shaft which engages the perforations and pulls the film past the picture aperture. This is coupled to a take-up spool (often by a slipping clutch system to compensate for the varying thickness of the spool as more film is wound on it). A transport lock comes into operation when sufficient film has been advanced for the next shot. At the same time the transport sprocket also works a film counter.

The film is carried in light-tight cassettes which are loaded into the camera in daylight. When the whole film is exposed it usually has to be rewound into its cassette before unloading, but in some cameras a second cassette takes the exposed film. In that case no rewinding is necessary.

Some miniature cameras take interchangeable backs or interchangeable magazines to permit rapid loading or film changing in the middle of a length. The interchangeable magazines themselves are loaded with standard cassettes of film, and carry suitable means of locating the film in exactly the focal plane of the camera. Usually dark slides and other safety devices prevent fogging of the film while switching over magazines.

Lenses. The majority of miniature cameras

have lenses with a focal length of 1¾ or 2 ins. (45 or 50 mm.). Some models, especially those using 18 × 24 mm. or 24 × 24 mm. negatives, have lenses with focal lengths as short as 1⅜ ins. (35 mm.).

The maximum apertures of miniature lenses range from *f* 3·5 upwards. A common value for less expensive models is *f* 2·8, while precision cameras may have lenses with apertures up to *f* 2 or 1·5.

Owing to their comparatively short focal length, the standard miniature lenses have a much greater depth of field than lenses of similar aperture on larger cameras. This makes the miniature specially suitable for all photography calling for the greatest possible depth of field at fairly large apertures without the need for critical focusing. The depth of focus is, however, very small, and the film track must therefore be very accurately machined to keep the film in exactly the right position.

Expensive miniatures may have interchangeable lenses with focal lengths ranging from under 1 to 40 ins. (20 to 1,000 mm.).

Shutters. Miniature cameras with non-interchangeable lenses are usually fitted with between-lens diaphragm shutters. A focal plane type is normal for models with interchangeable lenses, but there are also cameras of this type with diaphragm or rotary blade behind-the-lens shutters. A few cameras use a between-lens shutter in conjunction with a convertible lens system. In this arrangement the rear lens component and the shutter remain permanently on the camera, while the front lens unit is interchangeable to provide a range of focal lengths.

Most miniature cameras have the shutter tensioning movement coupled with the film transport to prevent double exposures.

Exposure Meters. Many miniature cameras incorporate a built-in exposure meter, usually coupled to the aperture and/or shutter speed controls. The meters are compactly designed selenium cell or cadmium sulphide type instruments. On so-called electric eye cameras with automatic exposure control an internal mechanism sets the aperture (or shutter speed) to the appropriate value for correct exposure on pressing the release button. Such models with exposure automation thus need no separate exposure settings by the user, beyond an adjustment of the film speed. The simplest types do not even have an aperture scale (except for flash and time exposures); more frequently however, shutter speeds can be pre-selected manually.

On interchangeable-lens cameras with focal plane shutter the exposure meter is frequently an accessory that clips on to the camera, but still couples with the shutter speed (and occasionally also the aperture) adjustment.

Flash. Simple miniature cameras and models with automatic exposure control are usually X-synchronized for flash; some models with diaphragm shutters have both X- and M-synchronization. Cameras with focal plane shutter are mostly X-synchronized for all types of flash at about 1/30 or 1/50 second; in some cases an M-synchronization for focal plane type flash bulbs is added.

A few miniature cameras have their own built-in flash gun. This takes the form of a miniature reflector which is either fitted in the front of the camera housing (often in place of an exposure meter) or rises up from the camera top. Such flash cameras mostly take the ultra-small AG 1 miniature bulbs.

Viewfinder and Rangefinder. The majority of miniature cameras have a direct-vision optical finder with a reflected brilliant image frame. The latter shows the field of view as well as a small area outside the subject field covered. The simplest cameras have a straightforward non optical (but cased-in) finder in the camera top. The present-day tendency is towards viewfinders that show an almost full natural-size image. This means that the view through the finder appears on the same scale as the view with the unaided eye.

Some of the cheaper, and most of the better, miniature cameras carry a coupled rangefinder. Where the lens is interchangeable, the rangefinder is coupled with a wide range of the available lenses. The rangefinder is nearly always combined with the viewfinder, so that the same eyepiece serves for both. This eliminates the need for changing over from one finder optical system to another between focusing and viewing. Older miniature cameras sometimes have separate viewfinders and rangefinders.

Camera Body. Nearly all miniature cameras have a rigid body, often of die-cast metal. The lens and shutter assembly is mounted on front (diaphragm shutter); on a few cameras with focal plane shutter some of the lenses are in a collapsible mount that can be extended and locked in the taking position, or pushed back into the body when not in use.

At one time a number of folding miniature cameras existed, using conventional bellows or cased in arrangements for extending the lens. Virtually no folding miniature cameras are on the market at present.

The camera back is usually hinged on, and swings right open for easy access to the film chambers during loading. Some cameras have a completely removable back. One or two designs only have a removable base and require the film to be pushed into a slot between the film aperture and the rear body panel. This can slightly slow down loading.

Types of Miniature Camera. 35 mm. cameras can be classified according to the basic characteristics.

Simple miniatures usually have a three- or four-speed between-lens shutter, simple viewfinder and little or no additional refinements.

Medium-class miniature cameras often in-

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

corporate a coupled—and frequently automatic—exposure meter, a wider range of shutter speeds, and better quality lenses. Occasionally medium class miniatures have a rangefinder, but this is rarer than an exposure meter. More advanced types feature both exposure meters and rangefinders, and vary mainly in the versatility of their shutter speed range and exposure automation.

Precision miniatures are made to the highest standards of fine-mechanical engineering. They usually have coupled rangefinder focusing, frequently with interchangeable lenses, and with a focal-plane or behind-the-lens diaphragm shutter. An exposure meter may also be built in.

The half-frame miniature, taking 18 × 24 mm. pictures, is often a scaled down variant of the full size miniature. Half-frame cameras tend to be comparatively simple models, sometimes with fixed focus lens, and automatic exposure control. They are mainly intended as a pocket companion camera, though some models exist with specifications approaching those of a full-size precision miniature.

The motorized miniature incorporates a spring motor which permits rapid sequence shots at a rate of up to 8 shots a second, with as many as 24 shots at one winding. The motor automatically retensions the shutter, transports the film and advances the film counter after every exposure.

A built-in battery-powered electric motor may do the same job.

The miniature reflex was originally built on the same lines as the larger single-lens reflex cameras, but has now been developed into a distinct type of its own. Present-day models often have an eye-level viewing arrangement for the focusing screen, showing an upright and, in some cases, right-way-round image. 35 mm. twin-lens reflex cameras are very rare.

Miniature Systems. Some of the more expensive precision miniatures have developed into an extensive and highly versatile system of equipment. Apart from the normal camera accessories (filters, lens hoods, cable releases, cases, etc.), this system includes specialized apparatus designed to adapt the camera for particular types of work.

Some of the accessories extend the scope of the camera. This group covers interchangeable lenses and viewfinders to go with them, simple close-up attachments, extension tubes and rapid winding gear.

Other more complex equipment converts cameras into specialized photographic tools for particular purposes, e.g., copying outfits, microscope attachments for photomicrography, reflex housings for tele- and close-up photography and stereo adapters for stereo photography. The basic unit of the system is in each case the miniature camera itself.

Miniature Conversion. A few roll film cameras of larger sizes can be adapted for using 35 mm. film by suitable conversion outfits. This may combine some advantages of the particular camera employed (e.g. reflex focusing in the case of a twin-lens reflex) with the economy of 35 mm. photography. However, the performance of the lens in relation to the size of the negative is not always as good as that of a lens specially computed for a genuine miniature; conversion can also only be successful if the camera to be adapted is made with sufficient precision to meet the demands of miniature technique. L.A.M.

MINIATURE CAMERA TECHNIQUE

The 35 mm. miniature camera, in spite of its limitations, is an extremely versatile instrument. The system of photography to which it has given rise is capable of good work within its own sphere.

The modern miniature camera has unique advantages, and a technique of its own. It is light and compact, so it is easy to carry and handle. It usually has a lens of wider aperture than that on bigger cameras and in some instances faster shutter speeds, while it holds negative material for a large number of exposures. In most miniatures it is possible to cut off and process part of a film, leaving the rest in the camera. There are miniatures with coupled rangefinders for precise and easy focusing and others with reflex focusing on a ground-glass screen. Most important of all, the best miniatures will take a range of lenses and accessories which make them almost universal instruments.

The eye-level miniature reflex with its pentaprism viewing system provides a direct view of the screen image at eye level. It is particularly easy to use with lenses of various (and variable) focal lengths and over focusing ranges from infinity down to a few inches.

But the miniature has no camera movements—i.e., front and back swing and tilt, rise and cross front, triple and double extension—and this explains some of its limitations in specialized commercial photography. However, by the use of extension tubes the absence of great bellows extension can be overcome.

The small negative calls for first-class material, exact exposure and development, and scrupulously clean processing.

Faultless photographs can only be pro-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

THE MINIATURE SYSTEM. The complete range of accessories of a precision miniature extends its scope to many applications. The most advanced 35 mm. miniatures thus comprise an almost self-contained system of equipment, to control the field of view, the scale of the subject, as well as operation.

A, interchangeable lenses may include focal lengths from around 1 in. for wide angle shots to 40 ins. or more for telephotography. B, C, and D, special finders for the alternative focal lengths clip into the accessory shoe on the camera. But many 35 mm. cameras indicate the fields of view of a selected range of lenses already in the viewfinder. E, a reflex housing in effect converts the rangefinder miniature camera into an eye-level reflex and is particularly useful for accurate focusing in telephotography with the longer focal lengths as well as for close-up work. F, extension bellows cover a continuous range of very near distances. G, subjects closer than about 3 ft. can often be covered with focusing adaptors which fit between the camera and lens, and also automatically adjust the rangefinder. H, micro adaptors permit the camera to be mounted on a microscope for direct photomicrography. A focusing eyepiece permits observation of the subject during exposure. J, distance gauges used with the extension tubes or supplementary lenses ensure rapid and exact placement of camera and subject when copying at selected fixed scales.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

duced by the miniature camera system with great care and skill, not merely in processing but right from the start—even before the picture is taken.

Cleanliness is an essential and calls for care in handling, carrying, storing and maintaining the camera and all its accessories and lenses.

Shutter Operation. Miniature negatives require a greater degree of enlargement than bigger sizes, so it is more essential to avoid camera shake. There are many satisfactory methods of holding the camera; the important thing is for everyone to find out which method gives him a firm, steady—and comfortable—grip on the camera and a simple, smooth pressure on the shutter-release. Each photographer must develop a shake-free shutter-release technique. A gentle squeeze with the most sensitive touch at the actual moment of release should be the aim. This calls for practice. Precise definition and dead-sharp negatives are impossible if there is the slightest trace of camera shake.

While it is possible, with some practice, to hold a camera reasonably steady during exposure times of 1/30 second or even longer, the high shutter speeds in nearly every case do give noticeably sharper results. Tests have shown that even with the standard lens many photographers get a small amount of camera shake—noticeable as unsharpness in big enlargements—at shutter speeds slower than 1/125 to 1/250 second. When no other considerations (such as a small aperture for adequate depth of field) make a slow shutter speed imperative, it is best to use the fastest available speed that gives a correct exposure.

For exposures with slow shutter speeds it is best to support the body and the arms against something solid for greater steadiness while releasing the shutter. A rigid support like a tripod is also useful, provided it is really rigid. The average light weight tripod tends to vibrate, and the "kick" of a focal plane shutter, and especially of the mirror of a single lens reflex camera may be enough to cause a slight image blurr even when the camera is mounted on the tripod. Often in such cases, and with shutter speeds between 1/15 and 1/60 second, the camera can be held more steadily in the hand (if well supported) since this tends to subdue camera vibration.

Using the Viewfinder. The eye should be as close as possible to the rear window of the viewfinder and must look straight through it. With simple optical viewfinders of the older type (without a brilliant luminous frame) oblique viewing gives misleading image boundaries. Even with brilliant-frame or bright-line finders the eye should be centred behind the eyepiece to take in the full image frame. Beyond this, the main problem is that of parallax—the slightly different fields of view taken in by lens and viewfinder owing to their different positions. With the standard lens only close shots of under 10 feet are affected. On some miniatures the necessary compensation is made automatically, in others the photographer must remember that his lens is looking from a viewpoint so much above, below or to the side of the finder, and make his own allowances.

When lenses of different focal lengths are used on miniature cameras, a variable type of viewfinder is often employed. This accepts various masks or allows other adjustments so that the viewfinder shows exactly the same field of view as the selected lens.

If the finder built into the camera has a multiple image frame for different focal lengths, the view taken in by lenses of various focal lengths can be checked directly, even before the lenses are changed.

In a single-lens reflex camera the screen visible in the finder shows more or less exactly the view taken in by the lens and no alternative finders are needed. Nor is there any parallax problem, since the lens itself forms the finder image.

Focusing. Correct focusing is an important part of successful miniature camera technique and can be achieved in more ways than one. Rangefinder focusing is a straightforward routine and, when the finder is coupled, the lens is automatically adjusted for focus as the images in the finder come together. It is usually more convenient to focus on some clearly defined edge in the picture if there is one. If the double image cannot be seen in the rangefinder window the chances are that the camera is not pointing straight at the subject unless the subject happens to be already sharply focused.

Another method of focusing is to estimate the distance and set the lens to the mark on the scale. This is useful when pictures must be taken unobtrusively and when to hold the camera up some time for focusing would attract attention. The greater depth of field given by miniature lenses makes such focusing techniques possible.

Zone focusing is a variation of this routine. The lens is pre-set at a distance where the depth of field at the aperture being used covers the near and far limits of subject movement. Pictures can then be taken without stopping to focus whenever the subject comes inside the zone of sharpness. This method is more successful at small lens apertures as the zone is then wider.

The image with the miniature reflex is focused on the screen. In some reflexes the sharpness of the picture can be checked over the whole screen area. More usually however only a central circle or ring actually shows the picture going sharp or unsharp as the lens is focused.

In addition many eye-level reflexes incorporate an optical wedge in the centre of the screen which acts as a split-image rangefinder. Here the image in the centre of field appears broken up across a horizontal dividing line, with the upper and lower halves displaced sideways relative to each other. As the lens is set

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

A MINIATURE REFLEX SYSTEM. As the reflex camera incorporates a universal viewing and focusing system, it needs fewer accessories to achieve the same scope as a rangefinder miniature. A, interchangeable lenses cover focal lengths from about 1 in. upwards. Ultra wide-angle lenses may be fitted in the camera if the mirror is swung out of the way. The reflex system is also ideal for zoom lenses. B, telescopic and other afocal attachments provide the equivalent of long focus lenses when fitted in front of the standard camera lens. C, extension bellows provide increased lens-to-film distances for close up and macrophotography. D, interchangeable finder units for eye-level or waist-level viewing. E, interchangeable focusing screen for alternative focusing possibilities with wedge rangefinders, fully matted screens, aerial images etc. F, copying or close-up stands (with or without lighting units). G, microscope adapter.

to its position of maximum sharpness for the subject focused, the two halves of the image join up and become continuous.

With some reflex focusing systems the image is broken up more irregularly in the central field, but again becomes smooth and continuous when the lens is sharply focused.

Rangefinder miniature cameras with interchangeable lenses and focal plane shutter can frequently be used with special reflex housings which in effect convert the camera into a reflex type. This is useful with long-focus lenses (since focusing on the screen is then more accurate than focusing by rangefinder), and for close-ups where the rangefinder cannot be used.

Grain. Compared to other larger negative sizes, miniature negatives require much more enlargement when prints are made. For this reason it is essential that adequate precautions should be taken to avoid objectionable grain in the image.

Where speed is unimportant, the slower fine grain negative materials are the better choice. However, to retain the fine grain, it is equally important to keep exposure to a minimum; over-exposure leads to coarser grain.

By using special fine-grain developers, further improvement results (although over-development will cause coarser grain). Most genuine fine-grain developers lower the film speed, although quite a few developers have been introduced which, besides giving finer grain, are actually claimed to increase the film speed.

The miniature photographer therefore can use a combination of film, exposure and development which will give perfectly adequate fineness in the grain. With the materials now available, grain presents no serious problems.

Exposure. On many modern miniatures exposure measurement is made convenient by a built-in exposure meter. Usually this is best suited for average reflected light readings, with the camera pointing at the subject. The exposure meter is in most cases designed to take in

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

approximately the same view as the camera lens. If the meter indication is visible in the viewfinder and the meter coupled with the aperture and shutter controls, it is only necessary to point the camera at the subject and adjust the controls until the meter needle matches an appropriate index mark or pointer.

Such readings are suitable for approximately 90 per cent of all subjects encountered; special corrections may have to be made for against-the-light shots, subjects of exceptional contrast or (in the case of reversal colour films) of exceptionally low contrast, and subjects of predominantly light or predominantly dark tones. Often it is most convenient to allow for this by an adjustment of the film speed setting.

With fully automatic exposure meters the meter mechanism itself sets the exposure control when the release button is depressed for taking the picture. The advantage of this system is that no separate exposure readings are required, but such exposure automation is often also less flexible when specific combinations of aperture and shutter speed have to be selected for depth of field or subject movement.

Choice of Equipment. The range of lenses and accessories of the miniature camera makes it possible to carry out a wide variety of work and to overcome some of the drawbacks of the absence of camera movements and the small negative. Excellent work can be done with one lens, but it is the extra equipment which gives miniature photography its enormous scope and advantages.

A suggested basic outfit ought to include at least the camera and its normal lens, with an ever-ready case, lens hood, cable release, tripod, and a photo-electric exposure meter (where this is not already built in). This equipment could be the starting point; the aim being to add other items when necessary. To some photographers the most important extra would be a longer-than-normal focal length lens; others would want a wide-angle lens or a lens of the widest aperture. Most good miniature manufacturers list a number of lenses of short, normal, long and extra-long focal length. The quality is not necessarily constant and the cost varies accordingly; but for miniature cameras, the higher quality lenses should be an automatic choice.

Close-ups. In the field of close-up photography the miniature camera is particularly efficient and there are accessories—e.g., supplementary lenses, extension tubes, and special equipment—which permit copying and close-ups to be made to a very high standard. A difficulty is that the viewfinder is no longer accurate at these short distances, but it is overcome by the use of special distance gauges, copying stands, and frame finders. With a miniature camera, hand-held close-ups are practicable and accurate range finding is often possible at close quarters by the use of a separate rangefinder or by an addition to the existing rangefinder.

With miniature reflex cameras close-up photography is much less of a problem. If the lens is not interchangeable, supplementary lenses can be used to extend the focusing range downwards. With interchangeable lenses closer distances are obtainable by extension tubes. In either case the screen of the camera finder system shows the actual subject area taken in as well as the exact sharpness of the image.

In close-up photography with increased lens-to-film distances (e.g. by the use of extension tubes or extension bellows) an exposure correction is required which depends on the scale of reproduction of the image on the film. The correction becomes significant at magnifications greater than about 0·12 (1/8 reduction) and rises astronomically in macro-photography at scales larger than same size. No such correction is normally necessary when supplementary lenses are used.

In all close-up photography the depth of field is very limited and it may often be necessary to work with small apertures and correspondingly increased exposure times. Under those conditions special exposure increases may be necessary to compensate for reciprocity failure effects, particularly with colour film.

The Miniature Approach. Good prints from small negatives are a result of several things:

(1) Correct exposure, because the small negative is not really suitable for after-work, so exposure faults are not easily remedied later.

(2) Perfect definition, because unsharpness can be particularly noticeable when magnified by enlargement.

(3) Standardized processing to cope with a long length of film containing up to 36 negatives, often covering a variety of subjects and lighting conditions.

(4) Maximum use of negative area, because with such a small frame available none of it should be wasted.

Tackling the subject with these points in mind wins half the battle. The other half concerns the choice of subjects.

The wide aperture lens makes hand-held shots practicable in poor light and makes possible easier night-time shots indoors and out as well as stage photography by ordinary stage lighting; circus pictures; seaside illuminations, etc. The convenience of the small-size camera makes it ideal for hand-held photography of subjects such as children and animals that are always on the move and do not stay still; for unposed natural pictures of everyday life; and for tours, holidays, trips abroad, and family events. The large number of exposures available at one loading is an invaluable asset in producing picture sequences.

The interchangeable lens system permits the subject matter to fill the negative every time, and provides the means for specialized work in industry, medicine, research. The system also enables good portrait, architectural and landscape photography to be undertaken, in spite

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of there being certain limitations in these fields.

The very great depth of field of the standard and wide-angle lenses is a useful feature; though it can also be a drawback where differential focusing is needed to isolate a subject from its surroundings.

The secret of good miniature camera work lies in thoroughly understanding the equipment and exploiting its advantages. A.H. (L.A.M.)

MINIM. Smallest of all units for measuring liquids. One minim is equal to $\frac{1}{60}$ drachm, or approximately an average drop. 20 minims correspond to about 1 c.cm.

See also: *Weights and measures.*

MIRED. Contraction of "micro-reciprocal degrees". The mired value of a light source is the colour temperature in degrees K divided into 1,000,000.

See also: *Colour temperature.*

MIRROR. Polished surface which reflects rays of light falling on it in accordance with certain optical laws.

Mirrors may be either flat or curved. They may be made of metal or glass.

Glass Mirrors. A glass mirror consists of a sheet of plate glass coated with silver on one side. For ordinary purposes, the glass side of the silver is used as the reflecting surface and the outside of the silver coating is covered with a protective coat of paint. Mirrors of this type keep their brilliance indefinitely because the silver coating is completely sealed. The only disadvantage is that the surface of the glass itself acts as a mirror and gives a weak secondary reflected image. Normally this is not troublesome, but it cannot be tolerated in optical and photographic apparatus for which front surface (often surface silvered) mirrors must be used.

Surface Silvered Mirrors. In this type of mirror, the polished glass is coated with silver, usually by cathodic sputtering. The glass in this case is merely a support for the silver film and does not protect it. Usually a very thin coating of transparent varnish is sprayed on to the silver to prevent it from being oxidized quickly, but even so, surface silvered mirrors tend to lose their brilliance and have to be resilvered from time to time. Silver is nowadays replaced by other metals and alloys, particularly aluminium deposited on the glass support by vacuum evaporation. In photography, the principal use for front surface mirrors is for the viewing mirrors in single and twin lens reflex cameras.

REFLECTION FROM A PLANE MIRROR. The image appears at the same distance behind the reflecting surface as the object is in front. Owing to its thickness, a glass mirror forms a secondary image by reflection from the front surface.

Half-Silvered Mirrors. The metallic coating on a glass mirror can be made so thin that it reflects only part of the light falling on it and allows the remainder to pass through without interruption. Half-silvered mirrors of this type are used in some optical rangefinders, visual exposure meters and microscope illuminators.

Diathermic Mirrors. Normally the silvering of a mirror reflects visible light as well as invisible ultra-violet and infra-red radiation equally. Reflecting layers can however also be made selective in their action, reflecting certain wavelengths of radiation and letting others pass through. This is analogous to the action of a dichroic filter. With selective mirrors, the aim is usually to reflect visible light but to let through infra-red radiation, and hence heat. Such mirrors are known as diathermic; typically they may reflect up to 90 per cent of the light (compared with over 95 per cent for fully reflecting mirrors) and about 10 per cent of the infra-red component.

Diathermic mirrors are used mainly to direct light into places where the attendant heat radiation is undesirable—for example as lamp reflectors in projectors, spotlights, etc. Some present-day projection lamps with integral or proximity reflectors use diathermic mirrors. In a projector this means that the radiated heat reaching the transparency or film is greatly reduced and consists almost only of heat coming directly from the lamp filament, while the light includes that concentrated by the mirror.

The mirror layer can equally be designed to reflect heat and transmit visible light. It would then act somewhat like a heat filter, with the advantage that it does not itself heat up to anywhere near the same extent.

Metal Mirrors. Mirrors may be made by giving a high polish to a metal surface by burnishing. The metal principally used is stainless steel but mirrors are also made by plating chromium on to a support of another metal. It is difficult and therefore very costly to produce a perfectly flat metal surface, and the reflecting power of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

REFLECTION FROM A CURVED MIRROR. Parallel rays of light are reflected back to a focal point. This is situated at a distance equal to half the radius of curvature.

the polished metals is not as high as that of the evaporated metal on glass mirrors. So the optical quality of commercially produced metal mirrors is rarely as high as that of glass and they are only used in places where a glass mirror might get broken by shock or heat—e.g., in some camera viewfinders and in the lamphouses of enlargers and projectors.

Curved Mirrors. Curved mirrors are used to serve the same purpose as a lens in many kinds of optical apparatus. A curved mirror surface behaves in much the same way as a lens with the advantage that it is completely free from chromatic aberration. A concave mirror behaves like a convex lens—i.e., it brings parallel rays of light falling on it to a real focus (but on the same side as the light source). A convex mirror behaves like a concave lens—i.e., it brings parallel rays of light falling on it to a virtual focus (behind the mirror).

Curved mirrors intended for forming an image are usually spherical—i.e., the surface is part of the surface of a sphere. A parabolic shape is used for mirrors intended to reflect a parallel beam of light—e.g., in lamphouses, motor car headlamps and searchlights. When the light source (which is as nearly a point as possible) is placed at the focus of the parabola, the resultant reflected beam is parallel and as wide as the diameter of the opening. Parabolic mirrors have the advantage that they can be extended to reflect most of the source's rays.

Cleaning and Resilvering. Ordinary mirrors may be cleaned by washing the glass with warm soapy water and drying with a chamois leather.

Surface silvered mirrors cannot be cleaned by ordinary means. The most that the user can safely do is to remove dust from the surface with a soft camel hair brush. Surface aluminized mirrors can be washed with a detergent.

When the silvering of a mirror becomes too dull or scratched it can be renewed. It is not worth the amateur's while to resilver a mirror.

See also: *Beam splitter; Heat filter; Mirror lens; Reflector.*

MIRROR LENS. Image-forming system using curved mirrors instead of transparent glass elements. Usually mirror optical systems use glass elements—which are easier to make in the high precision required—to provide the surface for subsequent silvering. Newton investigated the properties of both lenses and mirrors and came to the conclusion that lenses could never be freed from chromatic aberration. So he decided that it was better to use mirrors than lenses in constructing telescopes. His conclusions were later found to be incorrect, but mirrors are, nevertheless, more suitable for astronomical telescopes than lenses, because they produce much better axial images.

History. Spherical mirrors were first used in place of lenses in microscopes by Robert Barker in 1736. They were soon replaced by achromatic lenses, but in recent years a number of reflecting microscopes have been constructed under a grant from the Nuffield Foundation. These microscopes have aspherical mirrors of aluminized speculum metal for both condenser and objective and they give a numerical aperture of 0·65. They are used principally for infra-red and ultra-violet microspectroscopy for which they are particularly suited by their freedom from chromatic aberration. Reflecting microscopes employing spherical surfaces are now obtainable commercially.

The 200 ins. mirror in the astronomical telescope at the Mt. Palomar observatory in California is the largest in the world.

Advantages. An *f* 4 concave mirror will produce a practically perfect axial image, while if the mirror is made parabolic, even larger apertures are possible. By contrast, an achromatic lens telescope objective is limited to a maximum aperture of *f* 5 by its residual chromatic aberration. In astronomy, where the highest standard of definition is required, even the parabolic mirror is usually limited to *f* 5.

Disadvantages. Mirrors have the constructional disadvantage that they form an image which is in the path of some of the incident light, so blocking the centre of the initial beam and slightly reducing the aperture of the mirror.

TELEPHOTO MIRROR LENS. Typical of long focus mirror optical systems for miniature still cameras, this lens uses both refracting and reflecting elements. A, front corrector elements. B, convex secondary reflector. C, cone to keep out stray light. D, primary concave reflector. E, refracting lens elements. F, neutral density filters (the only means of controlling light intensity since the lens aperture is fixed). G, colour filters if needed. Lenses of this kind are produced in focal lengths from 500 mm. upwards.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Sometimes a second mirror is used to reflect the light and form the final image behind a hole in the centre of the first mirror.

Astronomical telescopes are normally used for photographing heavenly bodies, as well as for observing them; so in this specialized field, it can be said that mirrors have been used as photographic lenses for some time. Unfortunately, because of the large off-axis aberrations, telescope systems, whether made with lenses or mirrors, cover only a very small field, so they are not suitable for normal photography where a very much wider angular field is required.

Schmidt Mirror Lens. Bernhard Schmidt in 1931 developed a mirror lens which overcame many of the disadvantages of the telescopic system. The Schmidt camera employs a spherical mirror to form an image on the photographic film.

The aberrations of the mirror are compensated by a glass plate with an aspheric surface mounted at the centre of curvature of the mirror. The curvature of field is, however, very large and has to be overcome by using a special curved photographic plate. When this is done, it is possible to cover a field of 24° and work satisfactorily at an aperture of *f* 1·0, which is an extremely good performance for such a simple optical system.

Schmidt-type lenses have been improved by using spherical and plane instead of aspherical surfaces, and it is now possible to produce a mirror lens system with a flat field at *f* 1·0.

Extreme speed mirror lenses, with apertures to about f/0.6—are used for fluorography and other applications involving the photography of fluorescent screens. At this high aperture the field is no longer quite flat, and this can be allowed for either by incorporating a curved fluorescent screen in the camera employing such lens or by holding the film in a slightly curved plane.

By astronomical terminology the Schmidt camera has the photographic plate right inside the mirror system. Mirror lens systems for fitting in front of the camera are strictly speaking of the Cassegrain type, using two reflectors. The light path is thus folded back on itself twice.

Camera Mirror Lenses. Mirror optical systems are also used to an increasing degree as telephoto units for miniature and larger cameras. Usually these consist of both reflecting mirror and refracting glass elements. They are available from a number of optical manufacturers in focal lengths from 500 to 2,000 mm. and apertures of around *f* 4.5 to *f* 10. They are intended mainly for use with reflex cameras, since the long focal length necessitates very accurate focusing. Also the camera and lens assembly must be mounted on a very firm support; at the telephoto magnification of 20 × with a 1,000 mm. lens the very slightest vibration leads to unsharp pictures.

One characteristic of mirror lenses is that they cannot be fitted with an iris diaphragm to stop down the aperture. Light control therefore involves placing neutral density filters into the optical path, usually at the rear of the lens system. Colour filters are also placed in that position, since the large diameter of the front component (for example nearly 8 ins. with a 1,000 mm. f 5.6 lens) would necessitate prohibitively expensive large-size filters in front of the lens.

Book: *Optics*, by A. Cox (London).

MIRROR PHOTOGRAPHS. There is nothing difficult about taking a photograph of a scene reflected in a mirror. What the eye sees when it looks at the mirror from the camera position will come out in the photograph exactly as though the objects reflected were being photographed directly, but there are one or two points that must be remembered.

Focusing. The reflection in the mirror must be regarded as being as far behind the mirror as the object is in front of it, so the lens must be focused on that distance plus the distance from the camera to the mirror. It must not be focused on the surface of the mirror. For example, suppose the photographer is taking his own portrait and he is 3 feet from the mirror with his camera 1 foot in front of him. His reflection will be 3 feet behind the mirror and, as the camera is 2 feet in front, then the total distance from the camera to the reflection will be 5 feet. Accordingly the camera lens must be focused on that distance.

This simple relation only holds good so long as the camera is looking straight into the mirror. If it is pointed at an angle, to photograph objects lying to the right or left or above or below, then the focused distance must be equal to the distance from the camera to the object via the mirror measured along an imaginary line joining the two—i.e., along the path of a ray of light which proceeds from the object to the mirror and is reflected from the surface into the camera lens. This distance can be found by measuring from the object up to the surface of the mirror in the direction of the

FOCUSING IN A MIRROR. The total focusing distance is the sum of the camera-mirror and of the mirror-subject distances, i.e. the subject is focused as if it were behind the mirror.

reflection of the camera, and from that point on the surface of the mirror to the camera itself.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

With rangefinder or screen focusing, so long as the reflection and not the surface of the mirror is focused on, the image will be sharp, no matter what the angle of the line of sight or the distances of subject and camera from the mirror.

Effect of Glass. The ordinary domestic "looking-glass" is silvered on the back of the glass, and there is always a dim secondary reflection from the surface of the glass in addition to the bright reflection from the silvered surface. At a distance of several feet, this double reflection is not usually noticeable, but it may be objectionable in close-up pictures. The answer then is to use a polarizing filter in front of the lens, turning it until the surface image is no longer visible in the focusing screen—or when viewed directly through the filter.

The image reflected by the mirror is reversed from left to right. This does not matter with some subjects but it is undesirable in portraits and pictures where there is any printed matter. If the photograph is intended to look what it is, a mirror reflection, then there is no need to do anything further about it, otherwise the negative must be printed with the emulsion side away from the paper to cancel out one reversal with another.

Photographs may be taken of subjects reflected in the surface of distorting mirrors of the type set up in amusement arcades and fairgrounds. Here the same rule holds good as for plane mirrors, but it is not possible to fix the position of the reflection accurately. With rangefinder or screen focusing the lens should be focused on the important part of the reflection—e.g., the face—and a small stop used to bring as much of the rest as possible into focus. With a scale focusing camera, all that can be done is to set the lens as for photographing in a plane mirror and then use the smallest practicable stop to extend the depth of field sufficiently to cover any errors.

Where the mirror has a regular curve—e.g., spherical or parabolic—the image can be focused directly by rangefinder or screen in the normal way. But scale focusing by any of the methods described above is useless because the image may lie farther away from or closer to the surface of the mirror than the object reflected. The position of the reflection can be found from the fundamental optical equation if the focal length of the mirror is known. The focusing scale can then be set for the total mirror-reflection and mirror-camera distances. F.P.

MISONNE, LEONARD, ?–1943. Belgian pictorialist specializing in gum prints and bromoils of stormy landscapes with contre-jour effects.

MISSILE PHOTOGRAPHY. Rockets, satellites and other missiles are photographed in flight to obtain information about their behaviour and data for future improvements, etc. Such recordings can be made from the ground or from the missile itself. Photographs from missiles are also used for reconnaissance and survey work.

From the Ground. Two objectives of missile photography from the ground are the recording of events, and the acquisition of metric information. Event photography is performed by tracking telescopes, except for short duration events which may be done by high-speed cameras. Metric information of a missile may be obtained by cinetheodolites, or by ballistic cameras.

Event Photography. This is primarily concerned with the recognition of missile events such as changes in the plume and attitude of the missile and the changes of position from image to image, as well as its appearance. In the U.S., long focal-length telescopes have been used with 70 mm. cine cameras. Frame rates and focal lengths vary, depending on the problem being studied.

In one camera, for example, five effective focal lengths are provided from 100 to 500 ins. with corresponding fields from $1\frac{1}{2}°$ to $\frac{1}{4}°$. Pointing accuracy of 2 milliradians is obtained by two operators, one for elevation and one for azimuth, using stiff-stick controls capable of 10° per second tracking velocity. For remote operation, radar range signals are fed into the electronic computer and thence to the instrument to keep it on track by converting radar data to azimuth and elevation co-ordinates, as well as positioning the glass wedges for automatic focus control at all focal lengths.

The use of a 70 mm. cine camera provides time-coded sequential photographs of missiles in flight with high resolution. Tracking telescopes are typically mounted in a 16 feet diameter astrodome 30 feet above ground level to avoid atmospheric turbulence, and in an atmosphere air conditioned at 50 per cent relative humidity and within 5°F. of ambient temperature for protection against sudden changes of temperature.

Metric Photography. This is concerned with the accurate location and trajectory of missiles. Both cine cameras and plate cameras are used. Cinetheodolites are surveyors' theodolites to which a 35 mm. cine camera has been added to eliminate the surveyor's visual sight, while the missile is being tracked.

A true line of sight can be determined from the azimuth and elevation readings by noting the position of the target relative to the cross-hairs. Focal lengths in current use vary from the 12 to 180 ins. With two or more instruments arranged on accurately surveyed base lines a spatial position can be determined. Range accuracy is 15 to 30 seconds of arc.

For greater distances, a satellite tracking

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

camera is used as a ballistic camera. For such a camera, a large field of view and high optical speed are of prime importance. The lens is usually a mirror-optical system, a typical set-up may cover 5° × 30° with a 20 ins. focal length at *f* 1 and a film scale of 406 seconds of arc per mm. In operation, the camera alternately tracks the satellite and the stars at the rate of sidereal motion parallel to the satellite orbit, thereby exposing the satellite on a background of faint stars on a single film. The satellite's position is noted in relation to the exact centre of the middle break in the star trails.

For accurate trajectory measurements of missiles where resolution is secondary to freedom from coma and distortion, a more compact ballistic camera with a 12 ins. lens yields an accuracy of 2 seconds of arc over a 33° field of view. Where range is not limited by the brightness of the light source, the simplicity and portability of such a camera has led to its widespread use. An external capping shutter avoids the vibration and hot air turbulence caused by an electric motor operating an internal shutter.

An ideal triangulation system would provide a 45° cut angle from the base line between stations to the missile. If the angle from one station is given, the optimum angle from the other one is such that the sum shall be 90°. Three stations at the apices of an equilateral triangle close to 50 nautical miles with the launch, or nadir of the missile at the centre of the triangle and a fourth camera close (1 n. mile) to the centre provides an optimum set-up, although only occasionally achieved in a trajectory.

From Missiles. Photography from missiles may be for surveillance of the sky for other missiles or satellites, or for reconnaissance of the ground. The prime requirement is area coverage. TIROS (Television and Infra-red Observation Satellite) is a good example of a spin stabilized satellite camera. Originally a 104° field lens and later at 76° wide-angle lens covering 200,000 square miles was used to expose a 5/8 in. diameter Vidicon tube for 1/500 second, the image scanned in two seconds with 500 lines, and stored on reversible metallized magnetic tape for transmission on command.

The received image is photographed with a 35 mm. camera on a kinescope, and cloud depiction charts are prepared from the positive-film for distribution on facsimile circuits. In spite of many steps in the process, it has been possible to resolve ice floes in Canadian east coast waters.

The use of modulation transfer functions for each factor affecting the quality of an aerial photograph greatly aids the design of a photographic system. The lens function may be multiplied by the film emulsion function, the vibration function, the function for uncompensated linear image motion, the atmospheric wavefront disturbance due to boundary layer effects and "seeing" transfer function, to yield an overall performance curve, in which each individual factor may be varied to determine its particular effect on the system.

Photo-transmission systems from a drone or missile normally include a standard reconnaissance camera, either frame, strip or panoramic. This is followed by an in-flight rapid processor-slack box. The developed film is drawn past a high resolution film scanner and a high frequency airborne data link transmitter. The ground station receives the TV message and records it on 5-ins. film which is processed within a few seconds and viewed on a light table.

Due to the fact that the aerial camera can register more than twenty times as much information as the best TV camera, the transmission of this information cannot be continuous. Several minutes are required to read out each photograph, even at 20 megacycle bandwidths.

A special scanning tube has to be used to dissipate heat from the phosphor, The phosphor is deposited on a metal drum which acts as a heat sink and rotates the phosphor scanning area.

Rapid Processing. Silver halide films may be processed in 30 seconds or less by monobaths of low or high viscosity using spray cell, porous applicator, viscous applicator, or web methods of applying the monobath to the emulsion. Xerographic processes with a special film can achieve 200 lines/mm. resolution at an ASA speed of 20 with no liquid processing required. With the possible exception of photopolymers, this is the most promising type of film, where expense is no consideration, for photography from missiles.

Scope of Missile Photography. In its early history, missile photography was almost exclusively high-speed photography. As film speeds increased and instruments and their

CAMERA ORIENTATION CONTROL. A star tracker of this type may be used to keep a camera system in a missile vertical for accurate aiming. The sensing system permits lining up and following a fifth magnitude star within two seconds of arc accuracy. It works by photo-electrically monitoring the light coming through the optical tracking system. A, transfer lens. B, nutation wedge. C, condenser lens. D, gratitule surface. E, photo-multiplier cathode. F, solid catodioptric telescope. G, gimbal mounting.

associated environmental control improved, the short exposures needed to achieve high resolution became less important. Photographs above the atmosphere looking up have achieved 1/10 second of arc angular resolution, and looking down they have exceeded one second of arc.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Looking up from the ground, the wave-front deformation of the turbulent atmosphere limits the resolution to two seconds of arc, except under unusual conditions. The seeing strength factor is approximately proportional to square root of path length and inversely proportional to cube root of path elevation. Boundary layer turbulence from a high speed missile is proportional to atmospheric density and Mach number (speed relative to the speed of sound) and must be used as an additional factor in photography from missiles in the atmosphere. L.H.N.

MIST. Particles of water vapour suspended in the atmosphere. These particles tend to reflect the rays at the blue end of the spectrum, but they are more transparent to the rays at the red—and particularly the infra-red—end. The result is that light shining on to mist looks bluish-white, and light shining through mist looks yellow or orange.

When an object is seen through mist, the mist reflects the blue and violet rays and only allows the rays towards the red and infra-red end of the spectrum to pass through. At the same time, light falls on the mist from the observer's side and the opposite thing happens: the redder rays pass through the mist and away from the observer, while the violet and blue rays are reflected back towards the observer. So the object appears veiled with a bluish-white haze.

To the camera, matters are even worse, because the normal photographic emulsion is more sensitive to the blue end of the spectrum than to the red. So that in the ordinary photograph of a misty scene, the effect of the mist is much more noticeable than it is to the eye.

The effect of mist can be minimized by using a filter which holds back the violet and blue rays. Yellow, orange, and red filters are suitable; the deeper the tint of the filter, the less the mist will show in the photograph. If the mist is to be removed as completely as possible, as in the tele-photography of distant objects, a special infra-red sensitive emulsion is used in conjunction with an infra-red filter.

Pictorial Effect. Mist suppresses the details of the scene and leaves only the main masses visible.

It divides the whole scene into clearly defined planes, with near foreground objects appearing as very dark shapes, while those farther away become rapidly lighter in tone until the more distant simply merge into the general whiteness of the mist itself.

So mist photography is usually concerned with broad, simple ideas.

Exposure. Because the mist scatters light into the shadow areas of the subject, photographs taken in mist should be given a shorter exposure than indicated by any of the normal types of exposure meter or calculator (these guides to exposure always assume normally-lighted shadows).

The beauty of a mist photograph is in its softness; any tendency to over—or even full—exposure produces a negative with too much contrast for this class of picture. For the same reasons, development should never be continued beyond the recommended time, and a soft-working developer should be chosen. P.J.

See also: *Fog (atmospheric).*

MODELLING. Gradual variation of tone that helps to display the shape of an object. In two-dimensional photography the solid form of the subject can only be suggested—in particular by controlling the way in which the light strikes the subject. With the right arrangement of lighting, the form of the subject can be represented in terms of light and shade to give a more or less convincing impression of three-dimensional reality.

A ball illuminated exactly from the front will show little variation in tone and will look flat like a disc. If the light is moved more to one side, a shadow will appear on the other side of the ball; this shadow will follow the curve of the ball and so show its form more clearly. A light used in this way is often called a modelling light.

See also: *Lighting the subject.*

MODELS. The best way to obtain the services of a model, if the work justifies the expenditure of money for model fees or if it can be afforded, is to go to a model agency and hire a professional.

Agency Models. At the agency files show pictures of hundreds of models, all kinds of characters, men, women and children and young girls. The abilities and photogenic qualities of a model are easier to judge accurately by studying pictures than by interviewing the model in person. So it is better to consult the files of a large model agency for the talent required.

Even the amateur, if he has his heart set on producing really good pictures of living models, would do well to consider hiring a model from an agency. He will have to pay her for about two hours of work as much as the average working man earns in eight hours, but the result will almost certainly be far better pictures than he can hope to obtain with amateur models. If that were not the case, photographers would not spend sums running into thousands of pounds annually to hire professional models. If amateurs were as good

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

as the trained professional, there would be no room for the professional model.

Other Sources. Those who have no access to a model agency or who feel the expense is not justified need not despair. Good models of all kinds can be found in every city, town and village. It is only necessary for the photographer to seek them out, get them interested in posing, and find out by making test pictures which of them have the photogenic qualities he needs.

Character models of all kinds, including the glamorous girls who are always in greatest demand among photographers, can be found in the amateur theatrical groups. These amateur actors are willing and even eager, almost without exception, to be amateur models as well. And they are likely to have the unselfconscious qualities which make them at ease in front of the camera—a most important consideration.

For graceful girls with beautiful figures the most likely place to try is the local dancing school. Here the photographer is almost certain to find suitable models for bathing suit and figure studies among the dancing pupils. Poise and confidence are drilled into the dancing students from childhood, and the exercise of dancing practice gives them not only gracefulness, but the highly essential control of the pose.

They are also taught to control their facial expressions, and especially to be able to smile on command. False modesty is no part of their make-up; the dance student accepts naturally the sort of scanty costume that other girls would find embarrassing.

Dancers, too, will often pose in return for no other fee than a set of prints. It helps a dancer to check her technique to see herself in pictures, and if she ever becomes a professional she can made good use of them. But do not think of dance students only in terms of dance pictures; they are likely to be good models for any kind of photography.

Selection. Not all pretty girls make good models, so the photographer would do well to scrutinize the prospective model closely, with the following items in mind, before he commits himself to photographing her. Has she good teeth and pretty eyes? These are the features most difficult to retouch. Does she smile easily and naturally? A pleasant smile is a model's greatest asset. Has she a good bust line? This is an element of importance for bathing suit shots. Are her ankles trim? Trim ankles usually indicate a girl who will pose gracefully. Does she use her hands in a delicate way?

This is an important element in registering feminine charm on film. Is her posture good? The girl who habitually holds her head up and carries herself confidently will require less coaching before the camera than the one who slumps.

Is she self-confident? Humility is no virtue in a model. The best model is aware of her appeal, proud of her beauty, and happy about displaying it for the camera. Can she face bright lights without squinting? Note her reaction to sunlight; beware if she wears sunglasses.

Finally, does the idea of modelling appeal to her? Unless she is eager to co-operate, it is better to forget her. She should not be coaxed; no matter how beautiful she may be, she will be hard to photograph unless she co-operates whole-heartedly.

To determine the real extent of her interest, the photographer should give the prospective model his telephone number and wait for her to call for an appointment, rather than call her himself. This will weed out any whose interest is too mild.

Model Release. When a satisfactory model is found, she should sign a model release if the pictures are intended for publication.

The form approved by the Institute of Incorporated Practitioners in Advertising and the Institute of Incorporated Photographers contains the following details: name of photographer; negative series number; name of advertising agency or client; order number; product or service; and date of sitting.

This is followed by the body of the form, which reads:

In consideration of the sum of £..... which I agree shall be paid to me (or my agent) for posing for the photograph(s) referred to above, I permit..... and its licensees or assignees to use the photograph(s) and/or drawings therefrom and any other reproductions or adaptations thereof either complete or in part, alone or in conjunction with any wording and/or drawings for all advertising and editorial purposes in connection with the above product or service.

Unless otherwise agreed the photograph(s) and any drawings or adaptations thereof shall be deemed to represent an imaginary person.

I understand that I do not own the copyright of the photograph(s).

*I am over 21 years of age.

*I am not over 21 years of age but my parent/guardian has agreed to my undertaking this work and to the use of my photograph(s) as mentioned above.

*Delete as applicable.

This is followed by the name (in capitals) of the model, his or her signature and address, the date, and the signature of a witness.

A copy of the form must be supplied to the advertising agency/client with the photograph(s).

If the model is under legal age, the parent or guardian must also sign the release to signify his consent. E.M.H.

There are two ways of photographing a model: so that it looks like a model, or like the real thing.

Natural Representation. The photographer who aims at a natural representation makes no attempt to disguise the fact that the subject is a miniature replica of the real thing. So he can employ the normal techniques that apply when photographing other small objects—e.g., coins, ceramics, glass and silverware.

The common denominator in photographing most small things is a long focus lens, and so long as the camera can be equipped with one, the negative size matters little—a miniature camera is no better than a quarter- or half-plate instrument. The principal advantage of the miniature is its greater depth of field, but, as the subject is still, the lens of a bigger camera can be stopped down until the whole subject is sharp. Where the camera has no provision for fitting a long-focus lens, the only alternative is to take a small image on the negative and enlarge that part only.

The important point is that the camera should not be brought so close to the subject that the natural proportions become distorted. For this reason the subject should, preferably, be taken with its longest axis parallel to the focal plane—e.g., ships and locomotives should be taken in side view and not three-quarters or end-on. This is not, however, vital in the case of scale models photographed at a distance in proportion to their size since the perspective then remains the same. A side view will on the other hand bring out more of the detail which is often the main inducement to photograph a model.

As a rule the model-maker is proud of his work and, far from wishing to disguise its smallness, he may want to draw attention to the minute detail and the skill required to execute it. For this reason it may be useful to include another object in the picture for comparison—e.g., a tiny model might be supported on a match box. And although small objects are generally photographed with the camera down on their level, in this case a somewhat higher viewpoint adds to the miniature aspect of the subject.

Artificial light is generally more satisfactory than daylight because it can be controlled and the conditions can be exactly reproduced if there has to be a retake. It is always safe to use natural angle lighting—i.e., at 45° from the front and side—with plenty of fill-in light from a reflector or a second lamp near the camera. Reflections from bright metal or painted surfaces should be watched for and dealt with either by dulling them with a touch of putty, or by moving the lights.

The setting of the subject is best left absolutely plain apart from anything introduced to give the scale, and the background should be well below the general tone of the subject and free from distracting shadows.

Exposure should be determined by a photoelectric meter in the first place, but the best results will be obtained by actual trial, making exposures of longer and shorter duration than the meter reading.

In all other respects the subject can be treated normally. What is wanted is the presentation of a straightforward "catalogue illustration" because the interest is all in the detail and workmanship of the subject, and not in the photography.

Illusion of Reality. The difficult part of model photography comes when the miniature replica has to appear as the full-size object. The deception is rarely successful, particularly when the model is on a very much reduced scale. It is almost impossible to present a picture of a scale model to the eye so that its appearance is identical with that of the real thing. There are several reasons for this, the principal ones being bound up with the perspective, the definition and the tones.

(1) Theoretically the perspective of a particular model can only look right if the viewing distance is scaled down in proportion to the scale of the model. Suppose the problem is to take a photograph of a 1 : 30 scale model of a motor-car 15 feet long so that the observer will imagine he is looking at a photograph of the car itself. It would be reasonable to allow the subject in each case to fill two-thirds of the width of the picture. The real motor-car, photographed with a camera with a normal lens—i.e., of about 50° angular field—would fill two-thirds of the whole picture width from a distance of approximately 30 feet. To give the same perspective, the scale model

PERSPECTIVE IN SCALE MODELS. For correct perspective the model size as well as taking distance must be in proportion. To cover adequate angle, close-up lenses may be necessary.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

would have to be photographed from a distance of 1 foot. At this distance the lens would have to cover a picture width of 9 ins. so that the 6 ins. long model would occupy two-thirds of the picture.

But, with a normal lens, the angular field of about 50° only holds good so long as the subject is more than ten times the focal length distant. For close-up work, the lens must be racked out beyond the normal focusing range, and the further it is racked out the smaller its field becomes.

This diminution of the field of view is more pronounced, the longer the focal length of the lens. In theory it would at a distance of 1 foot be negligible only if the lens has a focal length of about 1 in. Lenses of such short focal length are only available for subminiature cameras.

In practice it will be necessary either to put up with a certain loss of angle of view (thus the model of the car would fill more than two-thirds of the negative), or to restore the normal field covered by using a supplementary close-up lens and leaving the camera lens set to infinity. The focal length of the camera lens then becomes immaterial, except in that it determines the image scale on the negative. The larger the negative image, the less enlarging it will need subsequently to yield natural perspective at a normal viewing distance of 10 ins.

If the scale of the model is larger, e.g. 1 : 15 instead of 1 : 30—1 foot long instead of 6 ins.—natural perspective would be achieved by photographing it from a distance of 2 feet. Or, by accepting a viewpoint twice as far away—60 feet instead of 30 feet (and accepting the perspective rendering that goes with this increased distance)—the 1 : 30 model could again be taken at 2 feet.

In the general case of a 1/x scale model, if this is photographed to reproduce the perspective of the original as seen at distance D feet, the camera must be placed at D/x feet from the model.

(2) In most cases the zone of sharp definition in the model photograph is much narrower than it would be in the real photograph it is seeking to imitate, and this inevitably reveals the deception.

Going back to the model motor-car: it was shown that a 1 : 15 scale model photographed 2 feet away would have the same perspective as the real thing looked at from 30 feet away. But even with a short-focus (e.g. 2 ins.) lens stopped down to *f* 22, the sharply defined field would start at 1 foot 10½ ins. and extend only to 3 feet 9 ins. So the foreground and background would both be out of focus.

If the same camera had really taken a photograph of the actual motor-car, even with a much larger aperture, the zone of sharp focus would have extended appreciably in front of and behind the subject—e.g., at *f* 8 the scene would be sharp from about 14 feet to infinity—

DEPTH OF FIELD IN SCALE MODELS. Top: *Actual subjects allow substantial depth.* Centre: *Close-up depth is limited.* Bottom: *So use small apertures and near backgrounds.*

an effect which it would be impossible to reproduce in the model set-up.

Sometimes it is possible to get around the difficulty by using a background set close behind the subject, but in that case the background scenery itself will be so close to the observer that its perspective too will have to be dealt with.

The fact is that it is generally impossible to reproduce the natural falling off in sharpness in the model set-up and this shortcoming will reveal the deception even if the perspective has been reproduced perfectly.

(3) Out of doors there is generally some haziness in the atmosphere that tends to soften and obscure objects progressively as they get farther away from the observer. The eye comes to accept paler tones and softer edges as indicating distance and sharp definition, and strong contrasts of light and shade as indicating nearness. This separation of the planes of the picture is a characteristic of outdoor subjects that is not normally present in model set-ups.

The Practical Approach. Although it is theoretically impossible to photograph a model set-up so that it looks exactly like the real thing, up to a point in practice some reasonably satisfying approximations can be achieved. Anyone who is aware of the limitations has a better chance of achieving something worth while.

The subject should always be photographed from the eye level of an imaginary 6 foot person scaled down in proportion to the model—e.g., a 1 : 50 scale model should be taken with the camera lens 6 × 12/50 ins.—i.e., about 1½ ins. above the ground level of the model.

The viewpoint should be as close as possible to the subject. At the same time it should not be so close that the resulting depth of field with the lens stopped right down is unnaturally restricted.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In this respect, photographing models differs from the photography of other small objects. It is the usual practice in such cases to use a long-focus lens and a distant viewpoint with the object of avoiding strong perspective effects. But the perspective which would look overdrawn on a full-scale subject photographed from a close-up viewpoint looks normal on a scaled-down model. This is because the subject distance is seen in relation to the scale of the model. In a photograph of a full-scale dog-kennel, a subject distance of 3 feet from the camera would appear too close, but with a 1 : 20 scale model doll's house in place of the dog kennel, the subject distance would be equivalent to 3 × 20 = 60 feet and would no longer appear uncomfortably short.

If a scale model is photographed from a distant viewpoint with a long focus lens, the perspective is unpleasantly flattened exactly as it is when a full-scale subject is photographed with a high-power telephoto lens.

If possible the background should be flat, and close enough to the subject to be included in the depth of field. A suitably scaled down picture of hoardings, a brick wall, a screen of tall trees, either painted or photographed, can lend an amazing feeling of realism. Any such artificial background must, of course, have its lighting at the same angle as the lighting on the subject.

Reduced-Scale Optical Systems. Special viewing instruments based on endoscopes can be used for a full-scale model from the proportionate distance and eye-level required to present the subject in its natural full-scale perspective. Here the optical system of a short focus telescope is mounted in a narrow tube terminating at a right angled prism. The viewer is set up so that the prism occupies the position of the eye of an imaginary model-sized observer. A real observer looking into the viewer gets a true impression of what the model would look like if it were scaled up to full size.

MODELSCOPE. The optical system of an endoscope, with a roof prism at the base, records close-up views of models as if a scaled-down observer were standing in the midst of the model scene. The camera (preferably reflex) is mounted on the unit.

If the eyepiece is replaced by a camera—preferably a reflex—the image can be focused and recorded just as it can with a microscope or telescope. This type of viewer is useful for photographing architectural models in life-size perspective. Another use is for taking still or moving pictures of model sets to project as a background to live action shots. The realism of the effect is derived from the fact that the primary image forming lens has a very short focal length.

This has the same relationship to the dimensions of the scale model as the lens of a normal camera has to a life-size set up. Accordingly both perspective and depth of field assume realistic values.

Camera Movements. A number of the difficulties of photographing models can be lessened by the use of camera movements.

The swing back helps to correct the distortion produced by looking down on the model. Even if the camera has no swing back, the same result can be achieved by keeping the camera level and photographing the subject on the top half of the negative. Without one of the means of correction it is impossible to show the top and front of the model at the same time without apparent distortion.

The swing front is used to extend the depth of field so that more of the foreground can be reasonably sharp. By swinging the front forward, the distance between the lens and the top of the plate is increased. This is equivalent to racking the lens forward to focus the nearer foreground.

The lateral swings are also useful for correcting any unpleasant convergence of horizontal lines when the camera looks at the subject from one side—i.e., so that the photograph will show something of the side as well as the front of the model.

Illumination. Lighting should present the subject in more contrasty tones than the background. The background should be softly lighted by a reflector or a well-diffused flood so that none of the shadows are as black as those of the subject itself.

If it is possible to introduce a third plane intermediate in both tone and position, it will enhance the feeling of depth and greatly improve the result.

When lighting for a natural effect, the modelling light should be kept at a distance

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

so that its rays have something of the parallel character of sunlight. Otherwise the distribution of shadows will look unreal.

Everything that has been said above assumes that the model itself is a perfect miniature of the real thing right down to the last visible detail. If the finish of any part is in any way below standard—e.g. showing an obviously abnormally thick layer of paint or a mark left by an apparently giant cutting tool—all the care and calculation spent on getting the perspective, sharpness, tones and lighting right will be wasted. F.P.

MOHOLY-NAGY, LASZLO, 1895–1946. Hungarian painter and photographer; professor at the Bauhaus. Experimenter in abstract photography and photomontage, 1922–28. He produced "photograms" by placing three dimensional objects on light sensitive paper and so produced contours, shadows and, in the case of translucent objects, texture also.

MONCKHOVEN, DÉSIRÉ CHARLES EMANUEL VAN, 1834–82. Belgian chemist and photographer. One of the foremost photographic scientists of the nineteenth century. Working in Vienna (1867–70) he built a famous studio for the photographer Rabending where life-size portrait enlargements were made. In 1878 perfected the preparation of silver bromide gelatin emulsions in the presence of ammonia. In 1879 improved the manufacture of dry plates and sold emulsion to dry plate factories. Later established in Belgium a factory for pigment papers. Also worked on spectral analysis and astronomy and improved the solar enlarger to which he added artificial illumination. Wrote on photographic chemistry and optics.

MONOBATH. Single solution combining developing and fixing chemicals, for simple and rapid processing. Monobaths for various materials are available commercially.

See also: *Developers.*

MONOCHROMATIC ILLUMINATION. Lighting with rays of virtually a single wavelength, used to eliminate chromatic aberration when maximum sharpness is required—generally in scientific photography and photomicrography. The sodium vapour and mercury vapour lamps are the commonest source of such light. The sodium lamp is now improved in its efficiency: one hundred lumens per watt, or more with lamps above one hundred watts. This increased efficiency is partly due to care in manufacture, but mainly to a good distribution of sodium along the lamp, due to the fact that pins placed in the inner tube allow sodium drops to collect at strategic points as the lamp cools.

Besides, the inner sodium discharge tube is enclosed in a larger tubular bulb, the two being separated by a vacuum, and this reduces the effect of ambient temperature.

Uses. The photographic lens can only accurately focus light of one or two particular wavelengths. It is true that at medium apertures the focusing setting provides sufficiently sharp focus for light of all wavelengths to which panchromatic emulsions are sensitive. Yet at these same apertures, photography by infra-red or ultra-violet radiation calls for an adjustment of the setting obtained by visual focusing, and at wide apertures such as *f* 2 the setting may not even be the same for red and blue. It follows therefore that, other things being equal, a record photograph exposed by monochromatic light will be sharper than if a wider band of the spectrum is used. In this way, all chromatic aberration is eliminated.

Sodium light is particularly useful for the photography of transparent or translucent objects, as modelling and depth are particularly well rendered without objectionable parasitical reflections.

Sodium and Infra-Red. As the sodium vapour lamp also emits rays in the infra-red band between 8,183 and 8,194 A., it can be used for infra-red photography provided that the visible rays are suitably eliminated by means of a filter. To facilitate striking, sodium lamps also contain a certain amount of neon, emitting both visible red and infra-red light, but the quantity is negligible in relation to the emission in the narrow band mentioned.

Using standard commercial infra-red emulsions, with maximum sensitivity between 8,000 and 8,500A. experimental photographs have been taken of documents and biological organs using both 250 watt incandescent lamps at 3,000° Kelvin filament temperature and a 140 watt sodium lamp. Of the two, the sodium illumination has proved preferable. Photographs of venous systems, showing the veins darkly against a white arm, gave negative density ratios of 20 to 45 per cent with incandescent and 20 to 75 per cent with sodium illumination. The resulting contrast in the positive in such cases is therefore much greater with sodium. Exposure times are much the same in each case, and focusing with sodium is effected visually by means of the yellow light, the lens extension being then increased by 1/200 of the focal length so as to bring the infra-red rays into focus. M.D.

MONOCLE. Simple spectacle lens, completely uncorrected, sometimes used for pictorial or portrait photography where the soft definition of the image is not undesirable. Otherwise used as a supplementary for changing the focal length of the camera lens.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MONOCULAR TELESCOPE. Originally developed for visual observation, monoculars are now made adaptable for photographic purposes. They enable a normal camera lens to be converted into a lens of longer focal length, the increase being dependent on the magnification of the monocular. In construction, monoculars resemble one half of a conventional pair of prism binoculars.

MONOPACK. Special form of sensitized material used in colour photography. It is a tripack of emulsions with intervening filter layers, coated on a common base. Each emulsion records one third of the spectrum. Also referred to as an integral tripack.

See also: *Colour materials.*

MONTAGE. Composite photograph made by cutting out parts of a number of prints and mounting them on a common support. The technique is used for producing trick photographs, making panoramas and aerial survey mosaics, and assembling photomurals.

Type of Prints. Some types of montage are purposely intended to appear as a collection of combined prints—producing a pattern or over-all impression. For this type of montage, the prints used do not have to conform to any critical requirements. However, for work in which the joins must be invisible (e.g., aerial survey), certain precautions must be taken in making the separate prints.

The scale of enlargement must be exactly the same for each print in the montage. This is best done by marking on the enlarger baseboard points where recognizable details appear in adjacent negatives (i.e., the overlapping edges of each picture); when the reference points of one negative have been thus recorded, and the print made, the enlargement of the next negative is adjusted until the matching details exactly fit the reference marks on the baseboard.

The illumination in the enlarger must be also perfectly even; falling off at the corners, producing light corners on the prints, makes it difficult to match the tones of adjacent prints.

All prints for the one montage should be made on the same paper, and to make the mounting as inconspicuous as possible, it is better to use single weight paper.

Cutting the Prints. It is important for the cut edges to be clean and smooth. This calls for sharp scissors or a thin, new safety razor blade. When a safety razor blade is used, the edge can be cut obliquely, so that the emulsion surface is undercut and comes to a thin edge, which can be stuck down more easily and so does not show up on the finished picture.

If both prints have similar types of blurred background—e.g., foliage—they can often be merged better if the foreground print (i.e., the one to be pasted on top of the other) is

CUT-AND-PASTE MONTAGE. CC-0. Agamnigam Digital Preservation Foundation Chennai

cut along an irregular line through the background, rather than along a sharp outline.

A special method of producing the outline is to score the print back with a razor blade and tear the print in such a way that the area required is pulled up away from the surrounding paper. This yields an irregular and at the same time thin edge which is often more easily hidden in assembling.

Assembling. Before mounting, the cut or torn edges should be thinned by carefully sandpapering the back edge of the cut-out print. This makes it easier to hide the join when the prints are combined.

If the edges of the paper base are still thick enough to be visible, they may be painted with water colour to match the local image tone.

The most suitable adhesive for finally assembling the prints is rubber solution, as it does not soil the print surface, and any excess is easily rubbed off.

At this stage, any minor faults are touched out and the composite print is re-photographed by copying in a camera to make a new master negative.

Montage is also used to assemble panoramas, and similar wide angle pictures. L.A.M.

MOOD. Emotion suggested by a picture. It usually differs from atmosphere (which is a natural quality), in being more the result of the photographer's personal interpretation of the subject.

MOONLIGHT. The light of the moon is made up of the same colours as daylight, but it is very much weaker (the sun is about 600,000 times more brilliant than the full moon). So the only real difficulty about taking photographs by moonlight is the length of the exposure. Even with a fast panchromatic emulsion and a wide-aperture lens, pictures of open landscapes call for exposures of fifteen minutes or more.

The apparent bluish colour of moonlight is due to the fact that in dim light the peak sensitivity of the eye is at a slightly different point of the spectrum.

Subject Movement. During an exposure as long as fifteen minutes, the image of the moon moves an appreciable distance, and if it is included in the picture area, it comes out as a long white sausage-shaped blur on the print. (Any stars in the picture area will appear as lines of light and not as points.) This is no drawback if the moon itself is kept out of the picture, but in that case there is a danger that the resulting photograph will be merely a flat and toneless view without anything to indicate that it was taken by moonlight.

Method. There are several photographic methods of including an image of the moon in a moonlight picture. The simplest method is to photograph the scene just after sunset a few days before full moon when the moon rises early in the evening. The exposure for the twilit landscape is about right for the moon itself so the moon may be included in the picture, and photographed at the same time as the scene.

Other methods rely on making two separate exposures; one for the landscape from which the image of the moon is excluded, and the other for the moon in which the exposure is so short that even if a part of the landscape is included, it does not register. The negative of the moon may be made by a second exposure on the same film or plate as the landscape, or it may be made separately and printed in afterwards like a cloud negative. The advantage with a combination print is that the same negative of the moon can be used for a number of different landscapes; the position of the shadows in the scene should, however, match the position in which the moon is printed.

Lens. If the moon is photographed with a normal angle lens, the resulting image is apt to look disappointingly small. For the picture to look natural, the image of the moon must be enlarged up to three times the size that it would normally appear in the print. This can be done by making the exposure for the moon through a long focus or telephoto lens with a power of 2× or 3×, while the exposure for the landscape is made through a normal angle lens. When the two negatives are combined and printed, the eye accepts the result as natural.

Alternatively, the moon may be taken through the normal lens, an enlarged duplicate negative made, and the latter combined with the landscape negative.

Exposure. Open landscapes under a full moon need an exposure of about 2–5 minutes at *f* 3·5 on the fastest panchromatic emulsion.

The light given by the half-moon is less than half of the light of the full moon; exposures under the half-moon should be at least three times the full moon figure—i.e., 6–15 minutes at *f* 3·5 on fast panchromatic film.

The above exposures will generally produce very dark shadows which help to convey the atmosphere of a moonlit scene. If the picture is to show the same amount of shadow detail as a daylight photograph, the exposures must be multiplied by four.

Equipment. Any camera that will take a time exposure is suitable for making pictures by moonlight. It should be mounted on a very steady tripod because of the long exposure times that have to be given. Preferably the camera should have both normal and long focus lenses so that the moon can be photographed separately on an enlarged scale for combination printing.

The lens aperture should be at least *f* 3·5 or the exposure times will be inconveniently long. The effect of stray lights and reflections is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

greatly increased by the darkness and the very long exposure, so the lens should be equipped with a really efficient lens hood. A piece of black card is useful for holding in front of the lens while lights of road vehicles are crossing the picture area.

Sensitive Material. While orthochromatic and slow materials can be used in moonlight photography, the fastest panchromatic plates and films are better, because they make for shorter exposures, less risk of movement during exposure, and consequently sharper pictures. F.P.

Image Amplifiers While normally instantaneous exposures by moonlight are impractical, they become possible with electronic aids such as image amplifiers. Since the amplification factors of such systems are well over 1000-fold, exposure times of a fraction of a second can record more detail than is visible under the lighting conditions by the naked eye.

Even cinematography is possible under such circumstances. A typical set-up might consist of a large-aperture lens (usually faster than *f*1) that projects an image on to the photo-cathode of the image amplifier, and another lens system that re-photographs the image from the screen of the amplifier tube on to 16 mm. film. An appreciable brightness gain also results from the fact that a large image is reduced to a small one and so concentrates the same energy into a smaller area, leading to a higher relative intensity.

See also: *Light sources in the picture.*

MORDANT. Substance which adsorbs and holds dyes specially strongly. In photography, mordants are used for dye-toning and certain colour printing processes where the silver image is converted into a mordant image in a mordanting bath, and then treated with a dye solution. The name mordant is also generally used for etching solutions used by block makers.

MORSE, SAMUEL FINLEY BREESE, 1791–1872. American painter and one of the inventors of the electro-telegraph. Met Daguerre in Paris and had a daguerreotype camera made late September 1839. One of the first in the United States to attempt portraits (September/October 1839, with exposures of 10 to 20 minutes). For a short time had a daguerreotype studio in New York (1840) in collaboration with Draper but soon abandoned photography.

MOTION PICTURE PHOTOGRAPHY. Alternative term for cinematography, especially on the professional level.

See also: *Cinematography.*

MOTION STUDY. In modern industry great importance is placed on economy in movement patterns of men and machines engaged in production. The design of the product and its method of use; machine and tool design, workplace layout and manual operations, all demand the achievement of the most efficient utilization of both effort and time.

The aspect of work study which deals with movement economy is known as motion study and is one of the most important activities of the work study engineer. It involves the analysis of movements into their basic functional elements. The work of the motion study engineer is to observe, or in the case of a new development to determine, the essential movements. He then analyses the records to work out the best movement patterns.

Motion study employs many specialized techniques of which photography is but one. The camera is especially useful in three main directions:

(1) For the analysis of movements which are either too rapid or minute to be appreciated readily by visual observation. This is known as micromotion study.

(2) For recording the paths of movement involved in a particular operation. This type of photographic record is known as the chronocyclegraph.

(3) For making general pictorial records of machines, tools, layouts and the like.

Micromotion Study. Micromotion employs a cine camera, usually taking 16 mm. films. The method is to take a cine film of an operation and include in the picture a chronometer graduated to read in 1/2000th of a minute. The resultant positive is projected frame by frame and examined to determine the points in time at which one basic element of movement merges into the next. This analysis is tabulated and studied and supplies the data necessary for the engineer to develop an improved method. The essential points to be observed in taking the film are to avoid heavy shadow areas and to

CIRCUIT FOR CHRONOCYCLEGRAPH INTERRUPTOR. A, high-speed relay coil. B, main switch. C, speed selector switch controlling flashing rate. D, make-and-break. E, variable resistance controlling lamp brightness. F, lamps.

CC-0. Agamnigal Digital Preservation Foundation, Chandigarh

fill the frame from a viewpoint which will permit all movements to be seen clearly.

Chronocyclegraphs. Micromotion is primarily concerned with the separate basic elements and particular movements and their relevance to the whole operation, but it very frequently happens that the path and amplitude of a complete movement which is a composite of many basic elements must be considered as a whole in a single picture.

This is where the still camera has the considerable advantage in that it makes it possible to record a complete trace of the movement—i.e., a chronocyclegraph. The technique consists in attaching to the moving member a small lamp which is made to flash at predetermined intervals by a suitable interrupter in the lighting circuit.

The lamps are switched on while the part is in motion and a normal brief exposure is made of such duration that it covers the whole cycle time. The resultant print shows the paths of movement as a series of white dots.

The interrupter apparatus is so designed that the intervals between the flashes may progress in steps from 8 to 30 per second. The current supply to the lamps is also variable so that intensity of illumination may be controlled for the various flash rates. A further characteristic is that the lamps light up at full brilliancy and die off slowly so that the flash produces a pear shaped image. The pointed end of the image indicates the direction of travel.

The following points must be observed in order to obtain the best results:

(1) The picture should fill the available area.

(2) A small aperture must be used in order to obtain a considerable depth of field.

(3) The photographer must be alert to recognize the beginning and end of the movement to be recorded. He must keep the shutter open only long enough to include the actual movement.

(4) The moving lamps must be powered to such an intensity that the print will show the series of dots with only a very slight image of the background or none at all. Sometimes it is preferable to superimpose a separate exposure of the background on the track of the movement.

In this way it is easier to control the lighting for each exposure.

The chronocyclegraph is useful for revealing momentary hesitations and delays which are indicated by merging of the spots. The chief value of this technique is as an aid in machine design, placement of jigs, fixtures and tools, locking devices on press tools, design of safety gates and other parts involving manual dexterity. The chronocyclegraph is invaluable in demonstration and training where it is often more convincing than a verbal explanation. This technique gains considerably in value if a stereo camera is used and the prints viewed stereoscopically. Relative distances are more easily defined, and movements in the plane of the taking lens axis are easy to resolve. J.H.

MOTOR RACING. Photographers who are also keen on watching motor racing naturally want to take pictures. Such pictures can be interesting and attractive records and are not difficult to get.

Equipment. Equipment must be specialized to some extent. A simple camera will only take pictures of racing cars when they are standing still; when they are moving they can only be taken with a camera with a good lens and shutter. The lens should have an aperture of at least $f3{\cdot}5$ and the shutter must be speeded to 1/500 second or faster. Normally the fastest panchromatic film should be used, but when a really bright day is expected it may be possible to use a slower fine grain film.

The most suitable camera for all-round photography of racing cars has a coupled rangefinder and direct (preferably frame-type) viewfinder. An interchangeable long focus lens is useful for the occasions when it is impossible to get close to the track. But if the photographer is content to limit his choice of subject and plan his course of action beforehand, he can still get good pictures with an ordinary camera without these refinements. In either

RACE TRACK SHOTS. Cameras with normal focus lenses are suitable for broadside or side-front shots on the inside and outside of bends (upper pair of cameras). Long focus lenses (lower pair of cameras) permit three-quarter or front views from farther back. Beware of the crash area just beyond the bend.

case, larger cameras are less suitable.

Position. The best position for taking the pictures of the race in progress is on the inside of the track at about 25 feet from the subject. As a rule, however, special permission (usually reserved for the press or the official race photographers) must be obtained for shooting from this position. At club meetings where attendance is restricted to invitation, the photographer can usually wander about as he pleases. Otherwise under ordinary racing conditions, the best position is as close to the track as possible.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The ideal position is on the track on the inside of a bend with the sun shining from behind the camera or across the line of fire but certainly not into the lens. The more light there is shining directly on the subject, the smaller the aperture that can be employed, and the greater the depth of field in which the subject will appear sharp. A shutter speed of 1/500 second should be used wherever possible and an exposure meter reading taken to give the aperture for this speed. (The meter must be aimed at the ground, not the sky.)

The photographer then stands as close to the bend as possible and sights and focuses on the line taken by the cars as they come towards him around the corner. The cars will naturally corner as close to the inside of the bend as possible and the photographer must take care that in his eagerness to get a picture he does not impede the view of the oncoming drivers.

As the car approaches it is kept in the centre of the viewfinder by swinging the camera, and the shutter is released as it passes over the spot previously focused on. The swinging movement of the camera must be smooth and steady and it should "follow through" even after pressing the shutter. Once this technique is mastered, sharp pictures can be obtained even with a shutter speed as low as 1/125 second unless the shot is taken on a bend.

(It is not generally realized that a car passing straight across the line of fire can be arrested with a slower shutter speed than one approaching direct or in three-quarters view. This is because the subject can be held absolutely stationary in the viewfinder when it is moving past the camera, but when it moves towards the camera, even though it is stationary in the finder, it is growing bigger as it approaches.)

By swinging the camera, the subject is made to appear sharp, but the background will of course be blurred. This is actually desirable in most shots as it increases the impression of speed.

For the photographer who has to go along with the crowd and do all his shooting from the public enclosures, the best position is on the outside of a wide bend. This is where a great deal of exciting duelling occurs and here drivers can often be caught fighting to regain control of a skidding car. At the same time it is advisable to keep away from the point on the outside of the bend directly in line with the oncoming cars because that is the point where crashes are most likely to end up.

There are also good pictures to be had from positions along the straight, but these call for very skilful panning to keep the cars steady in the finder when they may be travelling at well over 100 m.p.h. As conditions are constantly changing during the course of the race, it is as well to keep away from the grandstands which restrict freedom of movement.

At big crowded meetings, the photographer who is not adept at fighting his way to the ropes will find it a great advantage to get hold of a box to stand on.

Motor Cycles. Most of what has been said about motor cars applies to motor cycles, but there are one or two points of difference that need to be watched. Firstly, the motor cycle is a smaller target and calls for a closer viewpoint or a lens of longer focus than would be satisfactory for photographing cars.

Then the technique of cornering is different because the motor cycle has to lean over to counteract the centrifugal force. Generally speaking the racing car tends to corner wider and at a higher speed, relying on drifting and controlled skidding as much as steering for changing direction. The motor cyclist hugs the inside of the bend and leans over as far as possible just short of skidding. This makes the motor cycle a more impressive subject because the angle of the machine gives an added impression of speed that is absent with four wheels.

The best point for photography is on the outside of a sharp bend where the machines will be going relatively slowly and leaning well over. It is better to shoot a machine leaning away from the camera than towards it—i.e., shoot from the outside of the bend not the inside. This is because more light falls on the upper side of the machine and rider and more detail comes out in the photograph.

A broadside view from a low viewpoint is generally better than a three-quarter shot, but it calls for expert camera swinging and timing.

The corner is also the best place for shooting sidecar races. For such subjects it is important to take up a position on the sidecar side of the machines irrespective of whether this is on the outside or the inside of the bend otherwise the antics of the passenger will be masked by the machine and rider.

Club Meetings. The more homely club meetings can be just as interesting as international events and provide excellent practice for the photographer who wants to gain experience in motor racing photography. The cars at such events may not be the fastest, but they call for exactly the same technique as the star entries at international races.

There is a lot of interest to be had in photographing the various types of car present in the paddock. A stroll around usually reveals

VIEWPOINTS. Top: *Shooting upwards from a valley makes the foothill almost obscure the summit.* Centre: *Halfway up the other side of the valley the foothill, summit, and background are in proper proportion.* Bottom: *Too high a viewpoint dwarfs a mountain as more distant peaks tower above it.*

alpine plants, the gentian, the alpenrose, the saxifrages lend a special attraction to colour photographs of mountain scenery.

Viewpoint. Viewpoints on valley or plain level have the disadvantage that when the mountain subject appears in reasonable proportion it is too small and distant to be effective, whilst a near view, being practically below the subject, seriously distorts the perspective. Photographs taken from hill tops often miss the valleys and lower slopes. Viewpoints at intermediate levels offer the best chance of a good picture. When the foreground slopes away sharply it also opens up the valley vistas and it is surprising how the view expands even with a relatively small gain of height above the valley floor.

Climbing Shots. The recording of technical detail on rock climbs and on major mountaineering expeditions is an important part of mountain photography. For normal work with single lens cameras, extreme angles of tilt either up or down should be avoided. The best climbing shots are taken either from opposite the route by someone not in the party or among the party itself on traverses (i.e., horizontal movements across rock) or on ridges.

Stereoscopic Work. Stereoscopic photographs do not suffer from this limitation of tilt, and in fact pictures looking steeply up or down have astonishing realism and drama. But apart from climbing shots, stereo pictures of general views are unimpressive so long as the normal lens separation is used. There is, in fact, virtually no impression of depth.

Effective stereo shots of distant peaks are best taken with abnormal lens separation, sometimes with the left and right pictures made from as much as 100 feet or more apart. For such "long base" shots settled conditions without moving cloud shadows are essential. But such pairs reveal third dimensional detail unobtainable in any other way, and the mountain looks like a model a few feet away with all depth accentuated. C.D.M.

Books: *The Photography of Scenery*, by C. D. Milner (London); *The Mountain Scene*, by F. S. Smythe (London).

MOUNTANT. The important thing about an adhesive used for mounting prints is that it must not contain any chemicals which might attack the photographic image. For this reason, glue and gum should never be used. Many suitable types of adhesive are available: starch paste, dextrine, gelatin, rubber solution and dry mounting tissue.

Starch Paste. This is made from ordinary starch powder. A quantity, say two tablespoons, of the powder is placed in a basin. About a dessertspoonful of water is added and the starch is worked into a stiff paste free from lumps.

Boiling water is added (with constant stirring) to bring it up to the consistency of thick cream and at this stage is put into a saucepan and boiled for about two minutes.

A few drops of carbolic acid solution are then added and the mixture allowed to cool. When it sets, the skin which will have formed on the top is removed.

Dextrin. Dextrin mountant is best bought ready made and is used in exactly the same way as starch paste.

Here is a formula for those who prefer to make it themselves:

Dextrin (white)	14 ounces	350 grams
Water	20 ounces	500 c.cm.
Oil of wintergreen	5 minims	0·3 c.cm.
Oil of cloves	5 minims	0·3 c.cm.

The water is placed in a double saucepan over heat and when it has reached a temperature of 160° F. (this is critical) the dextrin is stirred in slowly. When it has dissolved, the preserving oils are added with constant stirring. This paste should be kept a week or two before using to permit it to mature.

Gelatin. Gelatin mountant has the advantage that the solvent evaporates rapidly so there is no danger of cockling the mount or print. One part of ordinary cooking gelatin is

covered with water and allowed to swell. This takes some time and the water must be changed several times during the period. The water is poured off and the soaked gelatin is heated in a water bath until it melts. Twelve parts of methylated spirit are added slowly while the mixture is stirred. It is then poured into a large wide mouth jar and covered. The solution sets when cool. It is melted again before use by standing the jar in hot water. It is applied quickly and evenly with a soft brush to the back of the print which is then placed as quickly as possible on the mount.

Rubber Solution. This adhesive has rapidly taken the place of the older mountants. It has the advantages of being very clean and easy to use. It adheres strongly, but if necessary, the print can be easily stripped from the mount. It is non-cockling. Several brands of adhesive rubber solution are marketed specially for photographic mounting.

Only these rubber mountants should be used for photographic prints; other rubber solutions may contain substances which are harmful to the photographic image in various ways.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

One drawback of rubber solution is that the rubber layer between the print and the mount gradually tends to lose its binding properties. The print may then start peeling off.

Dry Mounting Tissue. Dry mountants that cause adhesion when heat is applied are the least messy to use. Tissue impregnated with shellac is the most common and is usually sold in sheets or rolls interleaved with waterproof paper. Provided the tissue is used properly, really perfect contact between the print and mount can be achieved. The layer of shellac will also serve to protect the print from any impurities in the mount. Dry mounting tissue must always be stored in a cool and dry place to prevent it from deteriorating.

Solutions of thermoplastic synthetic resins are also used for dry mounting. These are brushed or sprayed on to the back of the print, and the latter can then be treated—once the resin is dry—like a print with dry mounting tissue already attached. R.M.F.

See also: *Adhesive.*

MOUNTING PRINTS

The print and its mount should always be truly rectangular. This can be ensured by careful trimming.

Trimming. The best trimmer is the desk type, operated by pressing down the top platform. In this type the necessary guide stop and margin indicator are incorporated. For prints up to 5 × 7 ins. the type of trimming board that has a push-down knife or guillotine is satisfactory.

Prints can, of course, be trimmed with a straight edge, using a set square as a guide. The print is placed upon a sheet of glass and cut through at one stroke with a very sharp knife or a safety razor blade in one of the holders sold for the purpose.

If the print has a white margin it is best to use as a guide a glass or Perspex straight edge through which the edges of the print can be seen: it is then easy to trim the print exactly parallel to the edge of the mask. When trimming a print without a white margin, the knife should be inclined slightly outwards. This will avoid leaving a white edge showing around the print.

Paste Mounting. The print is placed face down on a sheet of clean paper or an old newspaper. The mountant—e.g., starch paste—is then rubbed on the back of the dry print with the fingers or a brush (a discarded shaving brush is ideal). The brush is wiped across the print on all four sides on to the paper. This ensures that the edges, and especially the corners, are coated with paste. At this stage the print must not be allowed to slip over the paper because it is important to keep the paste off the front surface.

The print is next lifted carefully and placed in the correct position on the mount. This position should be indicated beforehand by light pencil marks. The best way is to attach the top edge, and then carefully lower the rest of the print into place to prevent air pockets between the print and the mount. A sheet of clean paper is then put over the print and pressure applied with a squeegee. The soiled paper upon which the print was pasted should be replaced by a fresh sheet for the next print.

Wet Mounting. Prints may be paste mounted when still wet if the excess water from the final wash is first removed by squeegeeing the prints face down on a sheet of glass.

The mountant is applied to the top print. It is peeled off, placed in position on the mount, covered with a sheet of white paper, and rubbed down into place. The surface of the print is then dried with a clean cloth, covered with a fresh sheet of paper and squeegeed firmly into contact with the mount.

Wet mounting should be avoided because when prints are mounted wet there is always a risk that the mount will cockle on drying.

Rubber Gum Mounting. The print is trimmed and its place on the mount is marked by two light pencil dots at the two top corners or by a rectangle ruled in pencil.

An ample supply of rubber solution is taken up on a palette knife and spread evenly over the rectangle of the mount, carrying it well beyond the dimensions of the print. The back of the print is then covered in the same way and both surfaces are allowed to dry for about a quarter of an hour.

The print is then laid in position, covered with a sheet of waxed paper, and squeegeed

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

METHODS OF MOUNTING PRINTS. Top sequence: *Basic stages in dry mounting with tissue.* 1. *Tack down a sheet of tissue. (slightly larger than print) to the back of the print with a hot iron.* 2. *Trim edges of tissue and print.* 3. *Place on mount and cover with clean paper.* 4. *Apply hot iron.* Bottom sequence: *Main steps in wet mounting with paste.* 1A. *Rub paste well into back of wet print.* 2A. *Carefully lower print on to mount.* 3A. *Wipe over to press down.* 4A. *Put print and mount under pressure for several hours.*

into contact with the mount. Once contact between the print and mount has been made, the print should not be moved. After about ten minutes the surplus solution around the edges can be rubbed away with the fingertip without harming the mount or the surface of the print.

Dry Mounting. Professional and commercial workers attach prints to the mount with dry mounting tissue. This is paper coated on each side with shellac which melts when heated in the dry mounting press and holds print and mount together. Prints mounted in this way do not cockle and the surface is left smooth and free from irregularities. The method is permanent because the tissue effectively stops any chemical impurities in the mount from getting through to the print.

A special heated press is necessary for dry mounting prints in any quantity and especially for the larger sizes. These presses are heated by gas or electricity and maintain the correct temperature for melting the tissue. The two faces of the press are very strongly constructed so that they will give the necessary high and uniform pressure all over the print.

A sheet of tissue, larger all round than the finished size of the print, is placed over the back of the print. The tissue is then touched down with a small heated fixing iron applied around the centre of the print. This melts the tissue and fixes it temporarily in position on the back of the print. Prints must always be quite dry before being mounted. There must be no dirt or grit on the print or the cover plate or it will indent the surface and ruin the print.

The print with the tissue attached is then trimmed and the tissue is touched down on the mount with the iron at all four corners. The tissue is then stuck to the print in the centre and to the mount at the corners, so that it holds the print in position ready for the mounting operation.

The bed plate of the machine is heated to 140°F. as indicated on the thermometer. The print, face up, is placed in the press with a metal cover plate on top of it and the pressure is applied for three or four seconds (prints on double weight paper need longer time). The print is removed and while still hot is bent outwards to remove the slight curl left by the press. If the print comes out of the press attached to the tissue and not to the mount it generally means that the press is not hot enough. If it is attached to the mount and not to the print the press is too hot.

It is possible to dry-mount a print with an ordinary domestic flat iron. The hot iron is first used to touch the tissue down on to the centre of the print and then, after trimming, on to the mount, exactly as the small fixing iron is used above. The mount and print are then laid on a smooth surface and a thin metal plate is laid on the print to act as a separator.

Pressure is applied with the hot iron over the whole area of the print until it is firmly stuck to

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DRY MOUNTING EQUIPMENT. Left: *Electrically heated dry mounting press for professional use.* Right: *Touching iron (may be electric) for attaching tissue to prints.*

the mount. This method is fairly satisfactory for small prints but less effective for larger sizes. It is not as certain in action as a real dry mounting press.

If a dry mounting solution is applied to the back of the print it is only necessary to let the solution dry thoroughly. The print is then placed in position on the mount, inserted in the dry mounting press and placed under pressure and heat as with dry mounting tissue.

Tape Mounting. Double-sided adhesive cellulose tape is also a neat means of mounting prints. When placing large prints on exhibition mounts it is advisable to attach only the top edge of the print. Smaller prints intended for albums can be mounted by two strips of adhesive tape attached at the top and bottom edges.

This is the procedure. Place the print face up on the mount and mark the exact position of the two upper corners with fine pencil marks. Then turn the print over on its face. Pull a length of adhesive double sided tape off its roll and stick it, with the free adhesive side downwards, on the back of the print near the top edge. If the print is to be fixed at the bottom as well, repeat with the second strip near the bottom edge. Next peel off the protective paper from the top of the adhesive strip, exposing the second adhesive surface. Place the print in position on the mount, holding it so that the top edge only touches the mount at an angle, with the adhesive surface of the strip well clear of the mount.

Align the print carefully with the pencil marks made before, and gently lower the paper on the mount so that the adhesive strip makes contact with the mounting board. Then press down firmly, running a soft cloth, (or a clean finger) along the print surface above the adhesive strip.

Print location must be correct the first time; once the adhesive strip has made contact with the mount it is rarely possible to move the print again without damaging the photograph or the mount or both.

Mounting for Exhibition. Prints may be mounted for exhibition by any of the methods described, but there are generally special conditions to be fulfilled. Most exhibition authorities stipulate mounts of certain standard sizes—20 × 25 ins., 16 × 20 ins. and 12 × 15 ins. are common. It is also usual to stipulate that the mount must be white or of light tone.

The size of the print is usually left open, but in most cases it will be found that the smaller the print the larger the apparent size of the mount. For example, a print 3 × 4 ins. would look well upon a mount 8 × 10 ins., but a print 6 × 8 ins. would look as if it had insufficient margin.

With the exception of the commercial mount where the position of the print is already marked, the photographer is free to decide the position of the print for himself. It is generally agreed that with vertical prints there should be more space at the sides of the print than along the top. And with horizontal prints there should be more space at the bottom than at the top; in fact a print mounted in the centre often has the appearance of dropping off the mount.

The best position should be found by experiment and marked before the print is finally mounted.

Fancy Mounts. Many workers attempt to enhance the appearance of their work by various more or less dubious embellishments such as mounting the print on a tinted mount or giving it a deckle edge. Such extras are almost always obtrusive and compete with the picture.

Pencil lines lightly ruled on the mount can be very effective, particularly if there are white areas running off the edge of the print. But the lines must be neat, rectangular and lightly drawn.

Titles and signatures on the mount are better left out unless the worker is skilled in the art of lettering. Unskilled lettering can easily ruin the appearance of an otherwise excellent print. R.M.F.

Books: *Enlarging*, by C. I. Jacobson (London); *The Complete Art of Printing and Enlarging*, by O. R. Croy (London).

MOUNTS. The main purpose of a mount is to isolate the photograph from its surroundings. Interest is then concentrated on the photograph and not attracted by detail outside the picture area. It also serves to provide the photograph with a stiff support.

The simplest mount is just a plain piece of card, coloured cream, ivory or white. A thickness of 1/16 in. is normally adequate.

Simple mounts are usually best, and exhibition prints are nearly always displayed on quite plain mounts varying only in surface and colour.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Colour. The image colour of a photograph can range from a cold blue-black to a warm reddish brown—or it can be toned to a variety of other colours. The actual paper base of the print can also vary from white to deep cream. So the colour of the mount must be chosen to blend with the print. A cream based print will tend to look degraded on a white mount; and although a warm toned print may be put on a white mount, it generally looks better on ivory or cream. Dark coloured mounts are best avoided, the only exception being for colour photographs, which gain in brilliance when mounted on a black or dark grey card.

Surface. Mounts are also available with different surface textures—e.g., smooth, egg shell, rough or with a linen texture.

Choice of surface is less important than colour but it does have some influence on the final appearance of a photograph. Pictures of a strong, bold character look better on rough mounts, and light delicate subjects need a smoother surface.

Size. If the mount is required only as a support, it is better to buy a size slightly larger than the print. The surplus border is then trimmed off after the print has been mounted. This leaves a cleaner edge.

When the mount is used to provide a border as well, there is no practical limit to the size that may be used, but the normal practice is to choose a size that will provide about 2 ins. border along the top and sides with rather more along the bottom. However, as mounts are made in standard sizes, the width of the border can only be varied by trimming the mount or altering the dimensions of the print. So unless a very wide border is required, a 12 × 15 ins. print is used on a 16 × 20 ins. mount or trimmed down slightly and used on a 12 × 15 ins. mount. A variation sometimes effective is to mount a horizontal print on a larger size vertical mount with the print near the top edge.

The standard sizes of mounts are the same as those for prints, but mounts are not normally made smaller than 6½ × 8½ ins. Most exhibitions have a rule that prints should be on mounts of a certain size. This is usually 16 × 20 ins., or 12 × 15 ins. but with minor exhibitions smaller sizes are often accepted.

Quality. It is important to choose a mount made specially for photographic prints. Ordinary mounting card may contain chemical impurities that will affect the permanence of the photographic image. Poor quality mounts also have a tendency to split along the edges, particularly when heat is applied—as in dry mounting.

Variations. Other variations on the simple mount are also used. The picture area can be cut out, and the edges of the opening bevelled. The picture is then mounted behind the opening so that it is framed by the mount. (Cutting out this aperture requires considerable skill.

Mounts can also be obtained with plate markings—i.e. with a sunken area slightly bigger than the print to be used.

Artists' drawing paper may also be used as a mount when firmness is not important. The most suitable is hand made paper, which has a very pleasing surface texture.

Coloured paper of a contrasting shade to the mount can also be introduced between the print and the mount. The paper is cut slightly larger than the print so that it will show a narrow border. With the right subject this narrow border between print and mount can look very effective. These papers, called border tints, are usually coated with shellac on one side for dry mounting.

Folder Mounts. In its simplest form, the folder mount is a piece of thin card folded in half. The picture is mounted on one half of the card, while the remaining half serves as a cover.

Folder mounts embody much the same features as the plain card mount, but are mostly made in smaller sizes and of much thinner card. They are also made in various colours with mottled and grained effects, deckled and torn edges and even with silver or gilt border lines.

To avoid the use of a mountant, folder mounts usually incorporate some easy system of attaching the print—e.g. four diagonal slits for the corners of the print (a method commonly used in albums). Another type has a cut-out frame stuck over the mount along three edges, the fourth being left unstuck so that the print can be slipped in.

Folder mounts are mostly used for small prints that are to be carried in the pocket or handbag. They protect photographs from surface marks and help to keep them flat. J.D.C.

MOVEMENT

If the subject of a photograph is moving as the shutter is released, its image will move over the surface of the film or plate in the camera. No matter how slowly the subject is travelling or how quickly the shutter opens and closes, the image is bound to move to some extent. Because of this movement the negative and any prints made from it will show blur. And if the negative is enlarged, the blur will be increased in proportion.

Even so, the blur is not bound to be visible in the finished print. In fact, if it is less than 1/100 in. wide the average human eye will not be able to detect it. With this as a starting point it is possible to lay down conditions for photographing moving subjects in such a way that the final picture will appear to be perfectly sharp—i.e., so that the actual blur will not be greater than 1/100 in. on the print.

Slowest Shutter Speed. If the negative is to be

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

OBJECT AND IMAGE MOVEMENT. Top: *The image movement is smallest for a distant moving object.* Centre left: *At a given distance a short focus lens gives a smaller image (with less movement) than a longer focus lens.* Centre right: *If, however, both negatives are enlarged to the same image size, the blur through image movement will be the same.* Bottom: *Object movement along the camera axis causes the smallest image movement, across the axis the greatest. Movement at an angle is intermediate in effect, as it can be resolved into a movement along the camera axis and one at right angles.*

used for making contact prints which will be viewed at the normal distance of 10 inches with the unaided eye, the condition to be fulfilled is simple: the image must not move more than 1/100 in. while the shutter is open.

In this case it is only necessary to calculate the time the image takes to move 1/100 in. on the plate, and the answer will be the slowest shutter speed that will arrest the movement of the subject.

For example, a racing motor car is to be photographed passing across the field of view 300 feet away at 120 miles per hour (176 feet per second), the negative is to be taken through a 10 ins. lens, printed by contact, and viewed from 10 ins. (these conditions give natural viewing). As the car (300 feet away from the lens) moves 176 feet in one second, the image (10 ins. away from the lens) moves (by simple proportion) (176/300) × 10 ins. = 5·86 ins. It moves this distance in 1 second, so that it will move 1/100 in. in 1/(5·86 × 100) or, roughly, 1/600 second.

This is the lowest permissible shutter speed (l.p.s.) that will arrest the movement of the subject at that particular speed, distance and direction of movement. For other shutter speeds, distances and directions, the corresponding lowest permissible shutter speed follows by simple reasoning.

If the racing car is travelling at 240 instead of 120 miles per hour, the slowest permissible shutter speed would be 1/600 ÷ 2 = 1/1200 second.

If the racing car is being photographed at 100 feet instead of 300 feet, the slowest permissible shutter speed would be 1/600 ÷ 3 = 1/1800 second.

Movement across the field is most marked; movement towards the camera becomes merely a relatively slow change in size. So if the car were moving towards or away from the camera instead of across the field of view, the l.p.s. could be made three times as long—i.e., 1/600 × 3 = 1/200 second. And if the car had been moving obliquely, at 45° to the camera-subject line, the l.p.s. can be twice as long—i.e., 1/600 × 2 = 1/300 second.

Effect of Focal Length. The above theory holds good for contact prints from negatives made with a 10 ins. lens and viewed at a distance of 10 ins. But if the negative is enlarged, then the blur is enlarged with it, and blur that was not noticeable in a contact print might become visible in an enlargement viewed at the same distance. So for every diameter the negative is enlarged, the l.p.s. must be made shorter in proportion—i.e., if the negative is to be enlarged four times, the above l.p.s. must be divided by four.

Generally, the amount of enlargement that must be given to a negative to produce a natural-looking print is found by dividing the focal length of the taking lens (in inches) into the focal length of the lens that gives a natural print by contact—i.e., a 10 ins. lens.

A negative taken through a 2 ins. lens must be enlarged 10/2 = 5 times to give a natural print. But the amount of blur in the negative is smaller in the same proportion because the film is 2 ins. away from the lens instead of 10. So that the l.p.s. for any particular moving subject is the same irrespective of the focal length of the taking lens.

But this is true only as long as the negative is enlarged to make a print for natural viewing at 10 ins. Very often, however, the subject is deliberately magnified beyond its natural print size either by taking the negative through a telephoto lens, or by giving extra enlargement to a negative taken through a lens of normal focal length (as when a 35 mm. negative, taken with a 2 ins. lens is enlarged 10 times).

If prints made in this way are viewed from a distance of 10 ins. they look so many times "larger than life" and any blur caused by

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

subject movement is magnified in the same proportion. Theoretically, the l.p.s. should be made correspondingly shorter—i.e., a negative taken through a 2 ins. lens and over-enlarged 10 times should be taken at half the l.p.s. for the same negative enlarged naturally five times.

Complex Motion. What has been said about simple motion can rarely be applied in practice because so many subjects involve more than one kind of motion. If a man is being photographed walking past the camera, a fairly slow shutter speed will arrest the movement of his body, but something very much faster would have to be used to give a sharp image of his hands and feet in the middle of their swing. The shutter speed that would arrest the movement of a railway engine would still leave the spokes of the wheels blurred.

In fact, almost every form of movement met with in practice is complex, and no photographer could hope to work out the exact minimum shutter speed necessary to arrest the movement of a given subject in time for the answer to be of any use. But a knowledge of the theory is a useful guide when adopting the more practical approach described below.

Focal Plane Shutter Distortion. In a camera with a focal plane shutter movement of the subject (or the camera) may distort the image on the negative even at shutter speeds fast enough to prevent blur. This is because the moving slit of the shutter exposes the negative piecemeal and not simultaneously all over. The speed of the shutter is the time taken to uncover and cover a single point on the surface. This may be so short that the image does not move enough to show blur in the print. But the total time taken by the shutter to expose the whole surface in this way is much longer and the image may also be moving as the slit moves across the focal plane. In that case each successive image strip exposed through the slit will be displaced further in the direction of the image movement, and the subject will appear to be sloping in that direction in the finished print. The wheels of a motor-car travelling past the camera will appear to be sloping either forwards or backwards if the camera is held so that the shutter travels from bottom to top or top to bottom respectively. If it travels from side to side, the image will be either compressed or elongated in the direction of movemet (i.e. round wheels appear oval).

The extent of the distortion depends on the time it takes for the slit to traverse the image. So the closer the subject to the camera—i.e., the bigger the image it forms—the worse the distortion. And the longer it takes the slit to complete its travel—i.e., the slower the speed of the blind or the farther it has to go—the greater the distortion. This explains why, under similar conditions, there is less distortion with a miniature focal plane shutter than with a larger type where the slit has a greater distance to travel.

Where this type of distortion is to be kept as low as possible, the subject should be photographed at the greatest acceptable distance and preferably with a miniature camera. On the larger focal plane shutter cameras the slit width and blind speed—i.e., spring tension—are adjusted independently. With such instruments it is possible to give the same exposure with several combinations of slit width and blind speed. Where there is a choice, that using the highest blind speed in conjunction with the widest slit gives the least distortion.

It must be remembered that what has been said above relates only to the image distortion produced by movement. The blur is controlled independently and in exactly the same way as with a between-lens shutter.

The Practical Approach. In practice the whole problem of photographing moving subjects is very much simpler than the theory suggests.

MAXIMUM EXPOSURE TO ARREST MOVEMENT. The figures indicate the slowest speeds that can be used when photographing a cyclist moving at about 15 m.p.h. at various distances from the camera. A subject moving at twice this speed (i.e., at 30 m.p.h.) will need twice as fast a shutter speed (half the exposure time—e.g., 1/100 second instead of 1/50), while the exposure can be doubled for a subject moving at half the speed (7–8 m.p.h.). The shutter speeds are of course approximate, and not necessarily marked on every shutter. Use either a suitable in-between setting, or where this is not possible, the next faster speed marked on the shutter scale.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The experienced photographer avoids movement blur in one or more of four ways:

(1) By shooting from a distance and angle that will minimize blur.

(2) By using the fastest shutter speed possible, irrespective of the theoretical l.p.s.

(3) By making the exposure at a "dead" point in the motion.

(4) By swinging the camera to keep pace with the movement of the subject.

Distance and Angle. The closer the camera is to the subject, the greater the blur on the negative, and at any distance, the blur is worst when the subject is moving across the field of view and least noticeable when the subject is moving towards or away from the camera. So if conditions preclude the use of fast shutter speeds the photographer should not work close to a moving subject, and he should choose a position where the direction of movement is not directly across the field of view, but at about 45° to the line of sight. (A head-on photograph would show even less blur, but the three-quarter view gives a better impression.)

Shutter Speed. From actual experience it is possible to make a list of the l.p.s. values that apply to a number of representative subjects, moving at various distances and direction. These values take into account any secondary movement of the subject (e.g., the arms and legs of a walking person, which move faster than the body) as well as its speed so they are more reliable than a theoretical list based on speed alone.

At the same time, the photographer cannot carry such a list in his head, and he will rarely have time to refer to it. In practice he simply uses the fastest shutter speed that the circumstances—lighting, lens aperture and film speed—will permit. In fact, within limits, the actual shutter speed used is less important than the other practical considerations governing the amount of blur.

The table below gives, however, a set of suitable exposure times.

The Dead Point. A swinging pendulum comes to a stop at each end of its swing; an athlete or a horse and rider at the highest point of a jump are moving neither up nor down; there is an instant in walking and running when the hands and feet are stationary. In almost every form of complex movement, there are "dead" points where the movement halts. These are the instants that the practised photographer looks for if he is out to avoid blur in his pictures.

It is not enough merely to be able to recognize the dead point; the photographer must learn to allow for the time lag in both the human and the camera mechanism, or he will find that he is making his exposures after the critical instant has passed.

Swinging the Camera. One of the most effective ways of minimizing the blur caused by straightforward movement is called "swinging the camera". This simply means that the camera is kept pointing at the subject as it moves past, the image of the subject being held in the centre of the viewfinder up to and during the instant of exposure.

When the camera swings with the subject in this way the subject will come out sharp on the negative, and the background will be badly blurred. But as a rule the blur, far from being objectionable, helps to separate the subject from the background and actually increases the impression of speed. Swinging the camera will render completely sharp only those objects which are solid units, such as cars, trains, etc., but there will still be evident a blurring in arms and legs of subjects such as human beings, as well as the limbs of animals.

General Technique. An experienced photo-

PRACTICAL SHUTTER SPEEDS FOR MOVING OBJECTS

Distance		*Exposure Time (seconds) for Object Speed of*								
ft.	*m.*	2 3·2	4 6·4	8 13	16 25	30 50	60 100	120 200	250 400	500 *m.p.h.* 800 *km.p.h.*
1	0·3	1/3000	—	—	—	—	—	—	—	—
2	0·6	1/1500	1/3000	—	—	—	—	—	—	—
4	1·2	1/750	1/1500	1/3000	—	—	—	—	—	—
8	2·4	1/400	1/750	1/1500	1/3000	—	—	—	—	—
16	4·8	1/200	1/400	1/750	1/1500	1/3000	—	—	—	—
32	10	1/100	1/200	1/400	1/750	1/1500	1/3000	—	—	—
64	20	1/50	1/100	1/200	1/400	1/750	1/1500	1/3000	—	—
125	40	1/25	1/50	1/100	1/200	1/400	1/750	1/1500	1/3000	—
250	80	1/10	1/25	1/50	1/100	1/200	1/400	1/750	1/1500	1/3000
500	150	1/5	1/10	1/25	1/50	1/100	1/200	1/400	1/750	1/1500
miles	*km.*									
¼	0·4	1/2	1/5	1/10	1/25	1/50	1/100	1/200	1/400	1/750
½	0·8	1	1/2	1/5	1/10	1/25	1/50	1/100	1/200	1/400
1	1·6	2	1	1/2	1/5	1/10	1/25	1/50	1/100	1/200

These shutter speeds apply for objects moving across the line of sight of the camera. For movement diagonally towards or away from the camera, the exposures may be 1½ times as long (e.g., 1/500 second instead of 1/750). For movement directly towards or away from the camera 3 times as long exposures may be given (e.g., 1/250 second instead of 1/750).

The standard of definition is 1/1000 of the focal length of the normal camera lens. With long focus or telephoto lenses the speeds must be multiplied (or the exposure *time* must be *divided*) by the power of the telephoto lens, e.g., 1/100 second becomes 1/200 with a 2× telephoto lens.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

grapher who wanted to photograph, say, a horse and rider clearing a hurdle, would go to work like this:

(1) He would choose a station which his subject would approach in three-quarter view and at which, at the instant of clearing the hurdle, it would fill about half of the picture space.

(2) Having decided what exposure to give he would achieve it with the lens aperture that would give a depth of field that just included the jump and no more. This would permit the fastest possible shutter speed in the prevailing lighting conditions.

(3) He would get rid of horizontal blur by swinging the camera as the horse and rider approached.

(4) He would get rid of vertical blur by clicking the shutter as horse and rider reach the highest point of the jump.

Deliberate Blur. Blur in a photograph of a moving subject is not always objectionable; there are times when a certain amount actually improves the picture. In fact the only photographs in which blur is completely out of place are scientific records of movements too fast for the eye to follow. In pictorial work it is rarely advisable to show both subject and its background perfectly sharp even when it is possible. If both are sharp the photograph simply looks as though the subject were stationary. F.P.

MOVIE. Originally slang term for motion picture, now applied to amateur aspects of cinematography. Thus an amateur cine camera is frequently referred to as a movie camera, and amateur filming as movie making.

(See also: *Cine camera; Cinematography; Cine technique.*

MOVING IMAGE PHOTOGRAPHY. Technique of stopping movement of an image relative to the film, caused by the object or camera moving during exposure. Also known as image motion compensation (IMC).

Fast shutter speeds, the conventional means of "freezing" motion, inevitably produce a blur, however minute, since the image moves while the shutter is open. The shortest exposure time can at best keep the blur within given limits of sharpness, depending on image speed. Often the fast (and grainy) film and wide lens apertures entailed themselves limit resolution. However rapidly the object or camera moves; optium resolution demands the complete elimination of all image motion.

This can be achieved by moving the film in step with the image or by moving the optical system. The speed and direction of image motion are assessed and the film made to travel at this speed, while the camera is aligned to match the direction. In this way, the image remains virtually motionless on the film. Alternatively, the lens may be swung or the whole camera panned to follow the object. The latter is of course the standard method of following movement and is, quite properly, a method of image motion compensation since, if accurately carried out, it causes the image to remain in one position on the film. But panning is not always convenient or even possible with heavy or complex apparatus.

Various means of moving the film are used. They include pulling it by the edges, holding it by suction to a moving platen or moving the back of the camera. The simplest method, however, utilizes the film transport mechanism, augmented by additional controls.

Image speed at the focal plane is calculated from the object or camera speed of movement multiplied by image scale—a function of lens extension (or focal length, if at infinity) and lens-to-object distance. Thus, if an object moving at 100 ft, per second is reproduced on the film at a scale of 1:50, the image travels at $100 \times \frac{1}{50} = 2$ ft. per second and the film must maintain this speed during exposure to record a motionless image.

Variations of the IMC Principle. The above applies to single-shot and intermittent (or repeating) cameras. The principle is taken further in continuous strip photography, exemplified by the Sonne aerial camera. Such instruments are shutterless, the film being

IMAGE MOTION COMPENSATION. As the object moves in front of the camera, the lens projects this moving image through a slit on to the film while the latter is transported at a speed corresponding to the image movement on the film itself. A, image on film. B, slit. C, lens. D, object. The initial position of the object and image are shown solid. A subsequent position during the movement is shown dotted.

exposed through a stationary slit across the focal plane. It is drawn continuously past this at the calculated image speed, the width of the slit being adjusted to give the correct exposure. So the effect is that of a focal plane shutter, but the result is a continuous record of objects passing the camera lens. The optical slit need not be at the focal plane: it may be placed in front of the lens or in the object plane. It can even be dispensed with entirely and a bar of light from a projector focused on the object plane instead.

CC-0. Agamnigam Digital Preservation Foundation and eGangotri

Factors Affecting Resolution. Since the image is virtually stationary, resolution should be the best of which the lens and film are capable. But this depends on several conditions. Object movement can be in one direction only: the film cannot for instance follow the vertical and random movements of a runner's legs as well as his horizontal travel. Again, any inclination towards or away from the camera will alter image scale and with it, image speed. For the same reason, the object must be in one plane, parallel to the film: it can have little or no depth because any background will be blurred, as in panned action shots of racing cars, etc. Even if this were not so, changes in perspective would still cause slight unsharpness.

Any form of moving film compensation for motion therefore demands precise operation. In aerial photography for example, accurate flying is essential, since any change in aircraft height, speed or attitude will affect these critical factors. Some limitations have to be accepted: the inherent difference in scale between the centre and edges of a photograph is one. Another is when the object is not parallel with the film: in this case the film movement is usually matched to the most important zone in the image.

Applications. IMC is used extensively in modern aerial photography, where high aircraft speeds and the extremes of resolution required make it mandatory. Standard air cameras can be adapted fairly easily by the addition of special IMC magazines; continuous strip photography requires a specialized instrument. With either, the focal length of the lens and the aircraft height and speed determine film movement, and these are often monitored and fed in electronically.

A variation of the continuous strip is a proposed aerial television system, in which the camera makes single line scans only, across the flight path below the aircraft. At the receiving end, the lines are printed off the tube face on to a moving strip of sensitized material. This advances at a speed equivalent to that of the aircraft, so building up a continuous picture of the ground underneath it. The principle is very similar to that of radio-facsimile transmission of pictures and documents.

Conventional document and microfilm copying methods often utilize moving image techniques to increase output; an image of the moving original or microfilm is projected through a slit on to sensitized material moving at a corresponding speed.

The Sonne principle has been applied to highway survey in America, using a 35-mm. continuous strip camera mounted on a boom on a truck. Image scale is predetermined by the camera height above the road and film movement is servo-controlled from the truck's speed. Floodlights on the truck give strong directional lighting to show up surface defects.

Race finish cameras work in the opposite way, the camera being stationary and pointing along the finishing line at the moving contestants. Blurred leg movements and any distortion due to inaccurately matched image speed is acceptable since the finishing line is a fixed point.

Moving image cameras are also used in industrial photography to examine regular surfaces, either by visible light or by X-rays. If the object is flat it is traversed past the lens; if it is cylindrical, it is rotated. In the same way, certain dental X-ray cameras take a panoramic view of complete sets of teeth on moving film.

Normal panoramic cameras may either themselves rotate about the rear nodal point of the lens or may sometimes have a rotating prism in front of the lens, scanning an arc. In either case the film is moved past a focal plane slit at a speed corresponding to the rotation. Alternatively, the lens and slit may turn together, wiping an image on to a stationary strip of film curved about the common centre of rotation. In panoramic work there is no change in perspective, so the object can have unlimited depth.

The moving image technique is useful in high speed photography, particularly in cinematography where conventional intermittent mechanisms would impose too much stress on the film. Instead, many high-speed cine cameras run the film continuously past the gate while keeping the image stationary on the film by means of a parallel-sided prism in place of a shutter disc. This turns in synchronism with film movement, deflecting the image rays throughout exposure in the direction of film travel. Even projectiles and rockets can be stopped in flight by the sweep image camera. It makes a single exposure on a strip of film curved about a rotating mirror which sweeps an image of a slit, and of the object passing it, along the film. Although not primarily concerned with making an accurate reproduction, when carefully set up, the camera can produce undistorted pictures of ultra-fast-moving objects. P.B.M.

MURALS. In the main, murals can be copied in the same way as ordinary paintings. But murals are usually much larger and may have to be taken in sections.

Since the process is apt to be tedious, before adopting it a careful check should be made to see if a suitable viewpoint for a single exposure has been overlooked (e.g., from outside the building, looking through an open window). When an immovable object (e.g. a lighting fixture or pillar), prevents a dead-on view, the camera may be placed off centre, if it is provided with movements for correcting parallels. If such a camera is not available, an ordinary off centre shot may be tried; sometimes it is possible to correct the resulting distortion at the printing stage.

If, however, there is no easy way, the mural must be photographed in sections. The prints are then assembled as a photomontage which is subsequently re-photographed. (The method cannot be used for murals in relief—e.g., sculptures—because the change of viewpoint causes a change in the perspective from section to section.)

Taking the Photographs. By using the focusing screen or viewfinder on the camera, a rough guess is first made of the number of separate exposures likely to be needed to cover the whole mural. All the exposures must be made at the same distance from the wall and the sections should be mapped out so that each fills as much of the available negative space as possible.

There may be only a single row or several rows—e.g., two rows of two, or one row of four. If the mural is an odd shape—e.g., on the wall of a stairway—it may have to be covered in rows of unequal numbers. The section plan must in any case allow for plenty of overlap.

Method. The camera is set up dead square with the wall at the end of a row so that the outside edge of the painting lies just within the field of view. An assistant then sticks a small white spot of paper on the mural just inside the field of view on the other side of the viewfinder or focusing screen. All four corners of the section are indicated on the mural in this way with white spots of paper lightly stuck to the surface.

A length of wire is then knotted to indicate the distance between the mural and a suitable reference point on the camera. (String is apt to stretch.)

After the first photograph has been taken, the camera is moved along the row until it covers the second section as indicated by the white spots marking the inner edge of the first section. Two new spots are then added to mark the inner edge of the new section. Before exposure the camera is checked to see that it is square with the wall and at the correct distance from it. The procedure is repeated until all sections in the row have been photographed.

For subsequent rows it is only necessary to attach one extra spot to mark each section. This also ensures the overlap between the two rows as well as between the two sections.

The lighting must be even over the whole of each section and must be identical for each exposure. Slightly darker or lighter corners can be passed off in a single print, but in a montage they show up the joins at once.

If it is necessary to use a filter to improve the colour contrast, it must be used for every exposure and not simply for the sections where the colour rendering requires it.

Making the Prints. The print from each negative should be as large as possible—although if more than a dozen are involved, the complete montage may be difficult to handle with prints much above quarter-plate size.

The enlargements should be made on single weight glossy paper with the enlarger perfectly square with the easel so that the scale of enlargement is the same for each edge of the negative. The illumination must be even to avoid dark or light corners on the prints. The enlargements may be numbered on the back in sequence with the negatives. Until a satisfactory set of prints has been produced, the enlarger should be left locked in its position on the column.

Apart from these precautions, no special technique is necessary until the prints are processed.

When the number of prints involved is not too great, it is best to process and dry all the prints together. Otherwise the agitation and development time and temperature for each print must be rigidly controlled to give identical tones.

Mounting the Prints. The montage is best assembled by dry mounting.

The base consists of a sheet of card or stiff paper large enough to accept all the prints and still leave a small border. Dry mounting tissue is tacked on to the back of each print and they are then trimmed just enough to leave clean edges. A print from a corner of the mural is placed on the corresponding corner of the card, leaving a slight border, and mounted with a dry mounting iron.

The remaining prints are mounted in the order in which the negatives were made, each overlapping its neighbour to give a continuous picture. If the detail on one print does not correspond with the next a fresh print of slightly smaller or larger scale must be made. This can be done by marking on a sheet of paper the actual position in which certain details should come, laying it on the enlarger easel, and adjusting the scale of enlargement

to fit the marks. In practice, slight errors in matching the edges pass unnoticed.

Next the montage is retouched. Dye white reference spots are touched out with dye and any discrepancies in the tones of adjoining prints corrected by building up the lighter tone by the edges with powdered graphite.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The montage is then copied, using normal copying technique and adjusting the lighting to minimize the effect of the joins. Soft, frontal lighting is best, so long as it is even and does not cause reflections on the print surface or shadows from the joins. J.D.C.

MUSEUMS AND COLLECTIONS

Photographic progress—technical as well as artistic—has been traced in a number of museums and collections throughout the world. Several national photographic societies have collection of apparatus and pictures from the beginnings of photography, and there also exist a number of famous private collections.

Great Britain. The photographic department of the Science Museum, London, has a fine collection of apparatus, both still and cinematographic—though many of its rarities are on loan from the Royal Photographic Society and the Will Day collection of cinematography. There are also on display photographs; these are not shown as pictures in their own right but only as specimens of various processes.

The photographs at the Victoria and Albert Museum, London, are not on display, but the collection can be used by the public. It lacks any historical sequence, being rather a conglomeration of photographs presented from time to time: chiefly portraits, topography, architecture, and art reproductions.

The Permanent Collection of the Royal Photographic Society of Great Britain, London, falls into three divisions: apparatus, books, and photographs. The collection of apparatus, including the items on view in the Science Museum, is, like the library, probably unrivalled. Both can be studied by members, and by students on special request.

A library catalogue was published in 1939 and a supplement in 1953. The collection of photographs contains large numbers of the Old Masters of photography in Britain, and the work of late-Victorian and Edwardian pictorialists is particularly well represented. Unfortunately the photographs have not yet (1964) been catalogued, and like the library and apparatus, are not on view to the public.

The photographic department of the Imperial War Museum, London, comprises about two million photographs from World War I onward, well indexed and available to the public.

The Kodak Museum at Harrow has an excellent technical collection largely devoted to apparatus, both still and cinematographic, and including the forerunners of cinematography. The range of exhibits includes the more important developments in the science of photography and examples of some of its industrial and other applications. The exhibits are not restricted to Kodak products, though naturally these form the largest proportion. The museum contains sections on colour photography and photomechanical printing. An informative illustrated catalogue was published in 1947.

One of the largest picture libraries in the world is the *Radio Times–Hulton Picture Library*, incorporating, in addition to modern photographs, the extensive historical collections formed by several private collectors, and the negative stocks of a few leading nineteenth-century photographic firms. The photographs are mainly collected from the "news" point of view, and include portraits of celebrities. They are classified in four sections: portraits, historical, topographical, and modern, in order to make them easily available to the public.

The National Buildings Record, London, formed at the beginning of the last war, contains about 800,000 photographs of English buildings and sculpture of historic interest.

Eadweard Muybridge bequeathed to the Public Library at Kingston-on-Thames much of his pioneer work (both negatives and published photographs) on the motion of human beings and animals, including his projection apparatus the zoopraxiscope, and his cuttings books.

The Reference Library, Birmingham, contains 22,000 social-documentary photographs and 14,000 negatives of the late-Victorian and Edwardian period taken by Sir Benjamin Stone and other members of the National Photographic Record Association.

The Scottish National Portrait Gallery, Edinburgh, possesses about 1,000 calotypes by Hill and Adamson, and several hundred of their negatives. The Edinburgh Public Library has about 450 calotypes by Hill and Adamson.

The Royal Scottish Museum, Edinburgh, has a few pieces of Talbot's apparatus, and calotypes by Talbot and John and Robert Adamson.

Other European Collections. There is no public museum in Europe devoted to the permanent display of photographs, much to the detriment of the appreciation of the past achievements of photography and its present-day applications in almost every sphere of civilized life. Nor does there yet exist an organized catalogue of photographic collections though it has been proposed by H. and A. Gernsheim that one should be published under the auspices of U.N.E.S.C.O.

Austria: The late Dr. J. M. Eder formed an historical collection, from the scientific point

of view, at the Graphische Lehr- und Versuchs-Anstalt, Vienna. The catalogue of the library, published in 1936, lists 7,500 books.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Belgium: The Musée de l'Histoire des Sciences (Science History Museum), Ghent, has a small photographic department chiefly consisting of apparatus, books and other relics of the Belgian chemist D. van Monckhoven.

Czechoslovakia: The National Technical Museum, Prague, has a large photographic and cinematographic department, dealing chiefly with the technical aspect.

Denmark: The Royal Library and the Royal Academy of Fine Arts in Copenhagen have large collections of historical architectural photographs—40,000 and 30,000 respectively. The Royal Library has, in addition, collections of photographic portraits and views.

France: In consequence of an arrangement whereby photographers can deposit copies of their pictures for preservation, the Bibliothèque Nationale (National Library) Paris, has numerically probably the largest collection of photographs in existence, which runs into several million. They are indexed under subjects and photographers' names. None are on display: in other words, they form an extensive pictorial archive. Foreign photographers are scarcely represented, and even leading nineteenth-century French photographers like Nadar are represented mainly by small published pictures (carte-de-visite and cabinet size). In 1955, the Georges Sirot Collection formed an important acquisition of exhibition prints and since then, other French private collections have been purchased.

A large and important historical collection, chiefly of apparatus relating to photography and cinematography and examples of processes, is on permanent display at the Conservatoire National des Arts et Métiers, Paris, which published a catalogue of its collection in 1949.

The Musée Carnavalet—the museum of the City of Paris—assembles photographic documents of Paris, and possesses many fine pictures by Marville and Atget.

Historically, the most important French collection is that of the Société Française de Photographie (French Photographic Society). It illustrates the development of photography in France both as an art and as a science from Niépce and Daguerre on, including apparatus. No catalogue has been published. Unfortunately the collection has been in storage for many years.

The Archives des Documentations Photographiques (Record Office of Photographic Documents) at the Palais-Royal, Paris, have a substantial collection of photographs of all kinds of subjects, including a large number of Atget's negatives.

The Archives Photographiques d'Art et d'Histoire (Record Office of Artistic and Historical Photographs), Paris, collect photographs of architecture, public monuments, and art reproductions.

An important private collection of about 1,500 daguerreotypes and some apparatus and books, assembled by Albert Gilles of Paris, was dispersed after his death and acquired partly by the Bibliothèque Nationale and partly by André Jammes, who assembled the most important private collection in France.

The Musée Denon, an art museum at Châlon-sur-Saône, possesses Nicéphore Niépce's apparatus and a number of his photo-etched plates (heliographs) and other relics relating to the pioneer of photography.

Germany: The Deutsches Museum (German Museum), Munich, used to have a good department before World War II devoted to the technical development of photography and some of its scientific applications, as well as an excellent range of cameras. The Museum was damaged during the war and the collection is still (1962) in storage.

A photographic museum was founded at the Stadt Museum (City Museum), Munich, in 1962, initially to house the collection of about 1,000 lenses and optical instruments of Dr. Loher. The Stadt Museum having been very active during the last few years in arranging photographic exhibitions, it is expected that the photographic museum will eventually also comprise photographs.

The Staatliche Landesbildstelle, Hamburg, owns, besides old photographs of Hamburg, an important collection of daguerreotypes by Hermann Biow, Carl Ferdinand Stelzner, and others, which were formerly in the city's art museum. In addition, there are collections of pictorial photographs *c.* 1900 formed by Dr. Ernst Juhl, and of contemporary German photography formed by Fritz Kempe.

There is a small museum of historical photography at Dresden, containing about 600 photographs by Hermann Krone, Hugo Erfurth, Franz Fiedler and other Dresden photographers.

The Staatliche Lichtbildstelle, Marburg, is a centre for photographs of German architecture and sculpture, analogous to the National Buildings Record, London.

The historical collection of Dr. Erich Stenger was acquired in 1955 by Agfa and will form the basis of a photographic museum at Leverkusen. Apart from photographs and apparatus, the collection contains an excellent library of books and journals.

A photo-historical collection is in process of formation at the Folkwangschule, Essen-Werden.

Holland: The Print Department of the University of Leiden has begun to build up a collection of photographs for which the Gregory collection of daguerreotypes and stereopictures forms the nucleus.

Following the showing of the Gernsheim

exhibition in 1956, the Print Department of the Stedelijk Museum, Amsterdam, decided to collect contemporary photographs of aesthetic value, as did several German museums mentioned above.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Italy: The Department of Antiquities and Fine Arts of the Town Council of Rome, and the Historical Museum of the Risorgimento in Rome, have photographic archives.

Sweden: The Technical Museum, Stockholm, has a collection of equipment and examples of processes. H. & A.G.

U.S. Collections. There are but two museums in the United States solely devoted to photography; the American Museum of Photography in Philadelphia, and the George Eastman House in Rochester, New York. The former is rich in the work of Philadelphia pioneers, particularly the brothers Frederick and Wilhelm Langenheim. In addition to a large collection of photographs, the museum owns many examples of apparatus.

The George Eastman House in Rochester, N.Y., occupies the palatial mansion built by George Eastman in 1905. To the existing building, a theatre seating 550 was added in 1950 for the presentation of moving pictures. The Eastman House contains an extensive collection documenting the entire history of photography from Daguerre to the present day. More than a thousand cameras, including examples of the earliest type, make up the technical division of the collection; the photographic collection (incorporating the collections of Gabriel Cromer and Alden Scott Boyer) contains outstanding examples of the work of daguerreotypists, calotypists, and later photographers. In co-operation with the Museum of Modern Art, the George Eastman House possesses the largest collection of moving pictures in the United States.

The photographic division of the Smithsonian Institution, Washington, D.C., contains perhaps the largest collection of early American equipment, including cameras used by the pioneers, Alexander Wolcott, Samuel F. B. Morse and John W. Draper, early motion picture equiment, and apparatus illustrating the development of sound recording.

Two important collections of photographs are to be found in Washington in the Library of Congress and the National Archives. Both of these institutions possess negatives of the famous Civil War photographs collected by Mathew B. Brady. To the Library of Congress there have come, year after year, photographs and early cine films entered for copyright, and as a result the collection is perhaps the richest in the United States. The National Archives own negatives and prints taken for government projects, including the remarkable early photographs of the U.S. West, taken shortly after the Civil War.

The Gernsheim Collection has been largely built up to illustrate the history and aesthetic development of photography. The 35,000 photographs range from the world's first, by Nicéphore Niépce, to the work of leading contemporary photographers and include exceptionally fine collections of the classics of photography, chiefly British, though leading nineteenth-century French, Italian and American photographers are represented. The collection also comprises apparatus (including forerunners of cinematography), autograph MSS, and a library of about 3,500 nineteenth-century books and journals and all important publications on the pre-history of photography from the sixteenth century on. An illustrated catalogue entitled *Masterpieces of Victorian Photography from the Gernsheim Collection* was published by the Arts Council of Great Britain on the occasion of an exhibition at the Victoria and Albert Museum in 1951. Since then, an enlarged international selection has been shown in art museums of many West European countries, and in the U.S.A. under the title 120 *Years of Photography*. In each case an illustrated catalogue was published the most expensive being that of the Detroit, U.S.A. exhibition (1963) with 1,020 items. The Gernsheim Collection is now owned by the University of Texas.

A few art museums have collected examples of artistic photography, notably the Museum of Modern Art and the Metropolitan Museum of Art, both in New York. Other museums are following the trend established by these New York institutions, and small collections are housed at the Chicago Art Institute, the San Francisco Art Museum, the Museum of Fine Arts in Boston, and other leading museums.

The important Epstean Collection of books and periodicals relating to the history and science of photography and photomechanical printing is at Columbia University, New York.

Historical societies often possess photographs by the thousand. Of the many predominant in the field, three can be mentioned in particular: the New York Historical Society, New York; the American Antiquarian Society, Worcester, Mass.; the Minnesota Historical Society, St. Paul, Minn.

One of the fields which seems to have attracted most individual collectors in America is that of stereoscopic photography. A review of American collections (by L. Dexter) in *Eye to Eye*, the journal of the Graphic History Society of America, revealed no fewer than twenty-one collections of sufficient importance to be described.

Two collectors have specialized in daguerreotypes: Mrs. Zelda P. Mackay of San Francisco, and Ray Phillips of Los Angeles.

An interesting collection of early cinematographic apparatus has been formed by Mr. D. Malkames in Tuckahoe, N.Y.

There is a growing interest in the history of photography, and other collections will no doubt be formed in course of time. B.N.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

MUSGER, AUGUST, 1869–1929. Austrian priest and professor of drawing and mathematics. Described in 1905 optical compensation (using a mirror polygon) for cinematography which led in 1914 to the manufacture of the Ernemann Zeitlupe (a high speed cine camera).

MUYBRIDGE, EADWEARD JAMES, 1830–1904. English photographer. Worked mainly on the West Coast of the U.S.A., taking landscapes. Produced the first serial photographs of humans and animals in motion by successive exposures (with 12 to 36 cameras) at regular intervals. Synthesized motion from these serial photographs in his Zoogyroscope (1879) and later in his Zoopraxiscope. Published 780 plates (1887) illustrating the human figure and animals in motion, taken under the auspices of the University of Pennsylvania. His work (1877–85) greatly stimulated other investigators in chronophotography, analysis and synthesis of motion, and in early cinematography. Retired in 1900 to his native town of Kingston-on-Thames; it is there that a collection devoted to his work is housed in the Public Library.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

N

NADAR (Gaspard Félix Tournachon) 1820–1910. French portrait photographer, previously caricaturist, writer and aeronaut. Became professional photographer in Paris, 1853, in collaboration with his brother Adrien and opened his own studio, 1858. Nadar photographed nearly all the great men active in Paris during the Second Empire and the Third Republic. Among the earliest to try electric light for portraiture, Nadar pioneered many fields; he was the first to photograph from a balloon, 1858, and underground (catacombs and sewers of Paris) 1861–2, and made the first photo-interview, with the centenarian chemist, M. E. Chevreul, 1886. Nadar patented balloon photography for ordnance survey, 1858. His exploits with his balloon *le Géant*, 1863, the largest in Europe, made Nadar an international figure.

During the Siege of Paris, 1870–1, he commanded an observation balloon corps and provided a balloon postal service. In 1874 Nadar lent his studio for the first exhibition of the Impressionist painters. Author of a number of books, including *Quand j'étais photographe* (1899).

See also: *Aerial survey; Balloons and kites.*

NAMIAS, RODOLFO, 1867–1938. Italian chemist. Made many valuable contributions to photography, especially in the field of colour work (mordant dye pictures). Evolved the permanganate reducer. Also established the photographic periodical, *Il Progresso Fotografico.*

NAPPELBAUM, MOISEI, SOLOMONOVITCH, 1869–1958. Russian portrait photographer. Opened his own studio in St. Petersburg, 1910 after working in Warsaw, Moscow and U.S.A. Made the best-known portrait of Lenin, and of many Communist Party Leaders, scientists and artists.

The only Soviet photographer to merit the title Outstanding Artist of the R.S.F.S.R. (Soviet Socialist Republics.)

NARROW GAUGE CINE FILM. Film of reduced width—as compared with the standard gauge 35 mm. motion picture film—for amateur cinematography. The most used gauges are 8 and 16 mm., and—to a lesser extent—9.5 mm. Also known as sub-standard cine film, though this term is going out of use.

See also: *Cine film.*

NATIONAL BUILDINGS RECORD. Independent organization which receives a grant from the Treasury through the Ministry of Public Building and Works. It was set up in 1941 when historic buildings throughout the country were being destroyed or damaged by enemy action.

It maintains a very large library of photographs of the historic architecture of England and Wales, which is arranged topographically in order of counties in such a way that any building, if it is represented in the collections, can be looked up at once.

There is also a considerable collection of measured drawings and specialized indexes of various kinds. The library is open to members of the public for reference purposes at all normal hours.

The Record deals with all types of buildings, domestic, ecclesiastical, and civic, dating from the earliest times to about the middle of the nineteenth century, after which its files are more selective. The collections are concerned not only with general views but also with details of interior decoration, fittings, and sculpture, the ecclesiastical sections being particularly rich in this respect.

The photographic library now contains over half a million prints. There is a small staff of permanent photographers who are at present engaged on specific programmes with a view to covering eventually the whole of England and Wales. Speaking generally, the important traditional architecture of the great cities and of the smaller towns has been covered, but there are many buildings of less importance in rural

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

areas which are not yet represented. Considerable attention is now being given to nineteenth century buildings.

One of the chief current duties of the Record is to ensure that adequate photographs and measured drawings are made—if they do not already exist—of all buildings of any merit that are likely to be demolished. Photographs of many important buildings demolished during the earlier years of this century are still required.

Photographs of a purely picturesque nature are not wanted. The Record is primarily interested in obtaining photographs which give a good and complete account of a structure both inside and out, with special reference to any significant architectural detail. It is also interested in photographs showing groups of old buildings in their natural setting, particularly in villages and towns where development may ultimately affect their appearance.

The collection of negatives numbers approximately 325,000, a great many of which have been given or bequeathed by interested persons. Specialized collections are purchased from time to time as funds permit. Prints are supplied to the public at normal charges. In those cases where negatives are deposited on indefinite loan the copyright of the lender is strictly observed. The Record is a non-profit making institution whose collections and facilities are freely available to all those who wish to make use of them.

See also: *Print libraries.*

NATIONAL PHYSICAL LABORATORY. British establishment founded in 1900 for the purpose of "standardizing and verifying instruments, for testing materials and for the determination of physical constants". The National Physical Laboratory, which is now part of the Department of Scientific and Industrial Research, covers 70 acres and employs more than 1,300 people. It is divided into nine divisions: Aerodynamics, Applied Physics, Autonomics, Basic Physics, Light, Mathematics, Metallurgy, Ship and Standards. In addition to its original objectives N.P.L. now carries out a considerable programme of fundamental research work and undertakes investigations of special problems.

The Central Photographic Section is responsible for a large part of the general and cinematic photography of the laboratory, including cinematography. It also gives advice on photography within the laboratory and to other government departments, industry, etc., and it is also part of the responsibilities of the section to provide photocopying service using photostat and microfilm processes and including plan-copying of engineering drawings. The section contains a lofty studio, 20 × 35 feet, with a gallery. Lighting, all of which is controlled from a mobile switching trolley, totals 60 kW and includes high-speed flash equipment. The studio is fitted with 10 feet wide roller backgrounds in different colours, as well as hanging curtains.

A variety of still cameras is available, from an industrial model extendible to 40 ins., to normal 35 mm. equipment. Both 35 mm. and 16 mm. cine cameras are used, as well as special high-speed cameras operating up to 8,000 frames per second.

The Section is also responsible for the installation and maintenance of all still and cine projectors in Glazebrook Hall, the Laboratory's new conference centre. The wide use of 2kW Xenon enclosed arc lamps is a notable feature of the equipment.

Photography is also widely used for specialized scientific purposes by a number of Divisions throughout the Laboratory. For example, in the Aerodynamics Division, various techniques of high speed photography over a wide range of framing rates are used for flow-visualization in wind-tunnels, shock-tubes and a water-tunnel, and for studies of boundary-layer transition. Cine films have proved of great value in making known the results of aerodynamic research, and there is a Divisional library of such films.

NATURALISTIC PHOTOGRAPHY. A book by Dr. P. H. Emerson appeared under this title in 1889. It was a manifesto of his belief in a return to nature for subject matter, pictorial photography having become bogged down in the artificiality of studio compositions. Emerson had some followers, but most of these became addicts of impressionistic photography a few years later.

NATURE PHOTOGRAPHY. Since the earliest days of photography the camera has been used extensively for making both pictorial and scientific records of nature subjects. To-day the camera is used to supplement the naturalist's notebook, to photograph plants, animals and insects not easily observed because they are too small, or appear only after dark, or because they are normally inaccessible to the student; while the camera has brought back pictures of the marine life and vegetation under the sea.

See also: *Animals; Big game; Biology; Birds; Botany; Fish; Flowers; Insects; Pets; Reptiles; Trees; Underwater photography; Zoo.*

NAVAL PHOTOGRAPHY. Photography in the Fleet Air Arm is limited to use of standard cameras as employed in the R.A.F. In training, for the calibration of weapons, and particularly in research, many special cameras are used both by the Royal Navy and by the Royal Naval Scientific Service.

Operational and Training Cameras. The cameras for training purposes include many standard commercial and R.A.F. cameras; they are used principally for the recording of data or for

CC-0. Ananingam Digital Preservation Foundation Chennai

accurate measurement of results of various operations. Cameras used at sea have to withstand exposure to bad weather, salt spray and continuous salt air and must necessarily be very robust and reliable. Simplicity coupled with very extensive weather-proofing are therefore the main criteria governing the design. Also the cameras have often to be used in restricted space and under very noisy conditions by relatively unskilled personnel, and the photographs must be taken at precise times when many other events are occurring. Because of this they are very strongly constructed and all operating levers, etc., are of generous proportions.

Dial Camera. The dial camera is used for purely recording purposes. This camera takes daylight loading roll film 2½ ins. wide, sufficient for some forty exposures on a 2¼ ins. square format. The lens works at *f*4·5 and has an accurate focusing scale from infinity to 18 ins. A very large brilliant viewfinder with parallax adjustment, which can be swung for viewing from above or from one side, is fitted. The camera can be fired by hand or by a built-in solenoid. The shutter is of the pre-set type, the pre-setting being done by the film wind mechanism which is actuated by a cord wound on a drum. This camera is often arranged to take photographs of the various dials, clocks and computing mechanisms in ships at the instant of gunfire or the launching of other projectiles.

Ballistic Recording Cameras. Much of the other purely naval photography consists in recording the falling of projectiles in the sea or the position of bursts of anti-aircraft fire in relation to targets. For these purposes the cameras are purely instantaneous recording measuring instruments, the lenses being calibrated for focal length and the resulting photographs measured and used for plotting purposes. A watch is also photographed at the instant of exposure to give the necessary time base for subsequent plotting.

One camera of this type is known as the Low Angle Marking Camera. The film used is 70 mm. wide and the picture size is 2½ × 6 ins. The shutter is of the louvre type, situated immediately behind the lens. A prism is fitted over half the lens, having a constant deviation of 80° so that each exposure actually takes two fields of view, one of the firing ship and the other of the fall of the projectiles. The camera is fitted with a sighting arrangement so that it can be kept aligned on the firing ship; a side mirror in the sight enables the operator to see the fall of shot so that he can make his exposure at the correct time. The film is transported and the shutter set by actuating a lever. Since this camera is generally used on the deck of a small ship it is fitted to the tripod so that it can swing freely and is partly stabilized by a heavy pendulum so that it remains upright while the ship rolls.

For recording high-angle gun fire against aircraft, slightly modified cine cameras are normally used by the Navy. One camera which is particularly favoured is eminently suitable for general use at sea because of the ease with which it can be adapted for many purposes and fitted with lenses, watches, counters, single shot devices, etc. The magazines are easily loaded and are fitted directly to the camera; there is no need to thread the film in the gate.

Photo-Theodolite. Photo-theodolites of a special type are used for calibrating various weapons. These are normally film cameras using film 5½ ins. wide with a fixed lens of 5 ins. focal length at *f*4. During exposure the film is pressed against a register glass which is ruled in accurate squares and the lens is carefully calibrated for distortion. The pattern of squares is thus transferred to the film at the instant of exposure and the position of any missile or splash can be measured in relation to the grid with considerable accuracy.

Two such photo-theodolites are used synchronously to mark the exact position of the missile in space. The cameras are mounted on levelling screws and are aligned accurately in fixed directions so that by simple trigonometry or graphical plotting the exact position of the missile can be calculated. The cameras are electrically fired in synchronism from a central observation point and the film is wound on and the shutter re-set by an electric motor. The camera is capable of recording at the rate of two pictures per second but, where more rapid repetition rates are required, as many as six such cameras may be rigidly mounted together in one framework, all actuated by a single main driving shaft with cams to fire each shutter in sequence.

Torpedo Camera. Another important camera is used to photograph the flight in air of torpedoes dropped from aircraft to determine the trajectory. In this camera, which uses plates 24 ins. long by 8 ins. wide, or in another version film 12 ins. wide and 36 ins. long, the exposures are made by means of a louvre shutter which is actuated by the movement of the sighting telescope. A moving mask in the focal plane covers the whole plate except for a narrow strip. This mask is connected to the sighting telescope in such a way that when the torpedo is centred in the telescope, the image in the camera coincides with the opening of the slit. The shutter opens each time the slit moves its own width. In this way a composite photograph is made showing the torpedo in successive instants during its flight and from this it is possible to analyse the trajectory.

Underwater Cameras. Underwater photography naturally plays a large part in Naval research and for this purpose several still and cine cameras in specially designed watertight cases are used with various types of lighting and flash gear. These cameras are used by free divers or frogmen. Cameras are also fitted in the

CC-0. Agamnigam Digital Preservation Foundation Chennai and eGangotri

hulls of ships to photograph underwater phenomena and some of these are of very special design although the actual film winding arrangements may be of normal types. It frequently happens that such cameras are driven synchronously with some machinery and exposed by means of stroboscopic electronic flash equipment. In all such underwater cameras the lenses are of special design for underwater use and are frequently of periscopic or telescopic types having relatively short focal lengths with a very long extension.

Cine Cameras. The need to record the images on television and radar cathode ray tubes has resulted in the development of special cine cameras having a long exposure with a very fast film change mechanism. In such cameras, the film may be exposed for 1 second and then moved into position for the next exposure in 1/100 second.

General Research. Research work for the Navy is carried out by the R.N.S.S. who maintain establishments dealing with all the multitudinous aspects of Naval work. Photography plays a very large part in much of the research work for which many special cameras have been devised. The cameras, however, although having novel features are normally of fairly well-known types. In particular image stabilized high-speed cameras of the drum type are largely used, some of them having repetition rates up to 50,000 pictures per second, each picture being 1 in. square. J.H.-D.

See also: *Air Force photography.*

NEGATIVE. In photography, an image on a film, plate or paper in which light or transparent areas represent the dark tones of the original subject and dark or opaque areas represent the light tones of the original.

The term negative is also used in electricity to define a contact which has a lower potential of electromotive force than an associated contact (the positive) or point connected in the same circuit.

NEGATIVE CARD. Name for a form of negative material, now little used, consisting of a negative emulsion coated on to a stiff card support. Positive prints are made by projecting the negative in a type of episcope, or by treating the card support with oil to make it translucent.

See also: *Paper negative; Supports for emulsions; While-you-wait photography.*

NEGATIVE CARRIER. Frame in which the negative is supported for projection in an enlarger.

An open frame (glassless carrier) is used for plates and miniature negatives, but the larger roll and cut films have to be sandwiched between glass plates.

NEGATIVE LENS. Lens which is thinner at the centre than at the edge, and which can form only a virtual image of the subject.

See also: *Diverging lens.*

NEGATIVE MATERIALS

Photographic negative materials essentially consist of a sensitive emulsion—which is nearly always silver bromide in gelatin—with or without other additions, e.g., silver iodide to increase speed and colour sensitivity. This emulsion is coated on a suitable film, glass, or (more rarely) paper, support.

There is a wide range of negative materials available to the photographer. One negative material may differ from another in any of the following respects:

(1) Speed.
(2) Colour sensitivity.
(3) Gradation.
(4) Graininess.
(5) Resolving power.
(6) Development characteristics.
(7) Physical characteristics of the emulsion.
(8) Nature of the support.

These properties determine the usefulness of a material for any particular purpose.

Speed. The extent to which an emulsion is light sensitive is usually referred to as its speed. This can be actually measured and expressed numerically in a number of different ways.

Originally the speed figures were derived from the minimum exposure needed to produce a certain degree of blackening on the film or plate after development. At one stage, comparative speeds were also arrived at by making a series of exposures of typical subjects, and examining the prints from the negatives to find the minimum exposure which will give acceptable prints.

Most current speed criteria are based on the exposure at which the characteristic curve reaches a certain minimum gradient.

Speed Systems. There are two practical types of speed system: arithmetical and logarithmic.

Arithmetical systems express the speed in cardinal numbers which are directly proportional to the sensitivity of the material and inversely proportional to the exposure needed for any subject. A film, for instance, with an arithmetical speed of 200 is twice as fast as one with a speed of 100 (measured in the same system). The slower film, therefore, needs twice as much exposure as the faster to give the same result. The most widely used current arithmetical system is the ASA speed (American Standards Association, also used in a corresponding British Standard). The Russian GOST standard uses a similar system, and so

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FILM SPEED SYSTEMS. In the arithmetic ASA system film speed is directly proportional to the speed number. In logarithmic systems the speed doubles for every constant increase in the speed number. Thus in the DIN range every increase of 2/3 corresponds to a doubling of the speed. On the ASA log scale every increase of 1° doubles the film speed. These three speed systems are fully interconvertible, being based on the same speed criterion. There are also other arithmetic speed systems with values similar to ASA.

do a number of now obsolete speed criteria.

Logarithmic systems express the speed in numbers which are logarithmic functions of the actual speed. In most of these systems every increase of approximately 3 doubles the sensitivity; every decrease of 3 halves it. For instance, a material with a speed of 26 needs twice the exposure for the same subject as a material with a speed of 29, measured on the same scale.

Arithmetical systems result in large cumbersome speed figures, whereas logarithmic systems give the same values in a much more convenient form. A range of 1 to 10,000 in arithmetical speed numbers corresponds to only 0 to 40 in logarithmic degrees.

The most widely used logarithmic system is the DIN scale current on the European Continent.

An alternative logarithmic scale (ASA log) increases the speed number by 1° for every doubling of the speed. Frequently ASA arithmetical and log numbers are quoted together: for example ASA 100/5°.

Materials of 25–400 ASA are mostly used for general photography. The fastest types (which may have speeds up to 800 or 1,200 ASA) are specially suitable for photography by artificial light or under poor lighting conditions.

Films and plates of 25–100 ASA are used in commercial and technical photography, where, for much of the work, a fast material is not essential, but where the characteristic advantages of the slower types—e.g., fine grain and high contrast—are more important for many of the subjects tackled.

Even slower materials are used for copying and reproduction and for photomechanical work where the high contrast required necessarily goes with low sensitivity. This is more of an advantage than a drawback, because it allows the material to be handled by a reasonably bright safelight during loading into the camera and processing.

The slowest plates of all are manufactured for making lantern slides and as such are not negative materials.

Speed Variations. The effective speed of a material also depends to some extent on how the exposure is given—i.e., by a bright light acting for a short time, or a weak light acting for a long time.

According to the classical reciprocity law (formulated in 1876), the exposure required to produce a given density or range of densities on development should depend only on the product of the intensity of light multiplied by the exposure time. The law does, in fact, hold for normal light intensities and exposures of the order of 1 second. But with very intense lighting and short exposure times (less than 1/1000 second) —e.g., in electronic flash photography and also in high speed spark photography—the effective speed of the material may be lower because of reciprocity failure.

This loss of speed (often accompanied by reduced contrast) is not related to the normal emulsion speed; it is more marked with some makes of material than others. Some materials are therefore more suitable for photography under such conditions than others of the same nominal speed.

A similar loss of speed arises at low levels of light intensity, requiring exposure times longer than 1 second, as in artificial light photography. The reciprocity failure can become very marked at extremely low lighting levels, as in astronomical photography. Frequently special emulsions are made for such applications, designed to yield their maximum film speed at low lighting levels.

The effective emulsion speed of films and plates also depends on the conditions of development.

Colour Sensitivity. A straightforward silver halide emulsion is sensitive over the approximate wavelength range 2,000A.–5,000A.—i.e.,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

COLOUR SENSITIVITY. Top: *Sensitivity of different types of emulsion over the visible spectrum, compared with the sensitivity of the eye (dotted curve).* Bottom: *Relative brightness of spectrum colours as the eye or the different emulsions would "see" them. In both cases, the curves and tones indicate: 1. Spectrum of uniform energy throughout (on which the other tone scales are based). 2. Sensitivity of the eye. 3. Ordinary blue-sensitive emulsion. 4. Slow orthochromatic emulsion. 5. Fast ortho material. 6. Normal panchromatic emulsion. 7. High speed pan emulsion with increased red sensitivity.*

to the ultra-violet and, in the visible region, to violet, blue and (slightly) to blue-green. It is insensitive to longer wavelengths—i.e., to yellow, orange, red and infra-red.

The limit of sensitivity at the short-wavelength end in the ultra-violet is fixed by the ultra-violet absorption of gelatin, but can be extended in certain ways (see below). The limit of sensitivity at the long-wavelength end depends on the properties of the silver halides themselves, but can be extended by means of sensitizing dyes. Different dyes extend the limit by different amounts, and the various types of colour-sensitive emulsions thus produced are described in the following sections.

This extension of sensitivity by means of dyes does not, in general, affect the ultra-violet sensitivity of the emulsion, or alter its limit. Also, all colour-sensitive emulsions remain more sensitive to blue-violet than to any other colour.

Non-colour-sensitive materials coated with unsensitized emulsions (sometimes known as "ordinary") are usually fairly slow, and can be handled by the light of an orange, olive-green or brown safelight. They are mainly used for copying from black-and-white line or half-tone originals, and for photomechanical work and document photography. They are also used in certain branches of scientific recording where certain characteristics obtainable only with such emulsions (e.g., high resolving power) are important.

Slightly Orthochromatic Emulsions. These emulsions are sensitive to ultra-violet, violet, blue, blue-green, and green light. They can be handled and processed in red light. Their excessive blue sensitivity can, where necessary, be reduced by a yellow filter, but this greatly decreases the speed, often to $\frac{1}{4}$ or less.

Slightly orthochromatic materials are used for copying and photomechanical work, and also to a limited extent in general and commercial photography.

Highly Orthochromatic Emulsions. These emulsions are sensitive to ultra-violet, violet, blue-green, and yellow light, but not orange and red. Materials coated with these emulsions must be developed by a deep red safelight or in total darkness.

These emulsions range in speed up to 500 ASA. They are used in general, commercial and technical photography. They are also used in those branches of spectrography where the red sensitivity of panchromatic materials is not required.

The excessive blue sensitivity of orthochromatic materials can be lessened by yellow filters which, however, reduce the effective speed (filter factor $1\frac{1}{2}$–$3\times$). A yellow filter shifts the zone of highest sensitivity from the blue region of the spectrum into the region where the human eye is most sensitive. This shift is taken advantage of in photomicrography where the image must be perfectly sharp. Using a yellow filter with a highly orthochromatic plate ensures that the rays by which the visible image is focused will also be the rays which form the photographic image.

If it is necessary in photomicrography to use a panchromatic emulsion to reproduce colours at the red end of the spectrum, the microscope must be fitted with an expensive objective with a very high degree of colour correction (apochromatic objectives).

Certain fast orthochromatic films are especially made for fluorography—i.e., the photography of X-ray images and cathode ray traces on fluorescent screens.

Panchromatic Materials. These emulsions are sensitive to ultra-violet and all wavelengths of the visible spectrum. Their sensitivity is usually lowest to blue-green, and they may therefore be developed by the light of a deep green safelight. But even this safelight must be used for very brief periods of inspection only; it is safer to handle and process panchromatic films and plates in total darkness.

Practically all films and plates for general photography, including amateur work, are nowadays panchromatic.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Usually the sensitization results in a reproduction of colour values in tones of grey which corresponds more or less to the visual brightnesses of these colours—except for the blue and violet region of the spectrum. Such materials are known as correct panchromatic (also orthopanchromatic). Certain special materials, and generally the ultra high-speed films and plates, have an increased red sensitivity and are known as red-panchromatic. This is useful in artificial light photography, since such materials lose little or no speed when exposed by tungsten filament lighting which is richer in red radiation and daylight (see below).

Panchromatic plates and films range in speed from very slow—for process work, copying coloured originals, spectrography, and photomicrography of stained specimens, etc.—to the very fast materials of about 500–1,200 ASA which are used in general photography.

While panchromatic materials are sensitive to light over the whole visible spectrum, their relative sensitivity to individual colours is not the same as that of the human eye. The human eye is more sensitive to yellow light than to blue and red, whereas panchromatic films and plates are more sensitive to violet and blue light, and (in the case of red-panchromatic materials) to orange and red, than to yellow.

Filters may be used to correct the oversensitivity of an emulsion to any particular colour, and also to alter the colour response to give contrast between areas that differ in colour, but which appear equally bright to the eye. The loss of speed of panchromatic materials when used with filters varies with the type of filter.

Infra-red-sensitive Emulsions. These emulsions are made by treating the ordinary emulsion with special dyes. This type of emulsion is sensitive to violet, blue, and blue-green light, usually insensitive to green and yellow, and sensitive to red and invisible infra-red rays. Infra-red-sensitive emulsions can generally be developed by the light of a special green safelight.

Although the emulsion obtained in this way is sensitive to infra-red rays, it is still much more sensitive to blue. When these special emulsions are used for taking photographs by infra-red light, therefore, the unwanted blue rays must be held back by a filter. Suitable filters are made of deep red or black glass which transmits only red and infra-red radiation. Infra-red-sensitive plates and films are, therefore, comparatively slow (80 ASA and lower) when they are used for photographing by infra-red radition alone.

Infra-red-sensitive materials are used extensively in aerial photography and photogrammetry. Infra-red radiation is not appreciably scattered by mist and haze. So it is possible to get clear pictures of distant landscapes on infra-red materials when ordinary photographic emulsions would be useless. Infra-red films and plates are also used in technical, industrial, and forensic photography, astronomical photography, and spectrography.

The range of wavelengths to which an infra-red emulsion is sensitive depends upon the sensitizing dyes employed. Infra-red materials for normal use are sensitized to wavelengths up to 8,800 A. (The sensitivity of panchromatic materials ends at about 6,600 A.) Scientific materials may be sensitized to wavelengths up to 10,000 A., while special sensitization has produced emulsions sensitive to wavelengths up to 12,000 A. for astronomical photography and infra-red spectrography. Such materials do not keep well.

Short Ultra-violet-sensitive Emulsions. These emulsions are used in scientific work, mainly ultra-violet spectrography.

All ordinary emulsions are sensitive to ultra-violet wavelengths down to about 2,000 A. But at short wavelengths the gelatin begins to absorb the radiations, and below about 2,300 A. this absorption seriously decreases the effective sensitivity. It also means that at short wavelengths the image is confined to the surface of the emulsion layer, and is therefore of low contrast. The resulting variation of contrast with wavelength is a disadvantage in spectrography. Hence for this work so-called "uniform-gamma" emulsions are sometimes used, in which the relatively excessive penetration of the emulsion by the longer ultra-violet wavelengths is prevented by the addition of suitable substances to the emulsion.

Sensitive materials to record the very short wavelengths in the region in which gelatin absorbs can be prepared in three ways. (1) By making emulsions which contain little or no gelatin (Schumann plates). (2) By making the silver halide grains project above the surface of the gelatin layer, thus reducing absorption by the gelatin to a minimum. Such emulsions are very easily damaged. (3) By sensitizing or coating the film or plate with fluorescent materials which glow with visible light under the action of ultra-violet rays. The fluorescent material may have to be removed before processing.

Daylight and Artificial Light Speeds. The spectral composition of daylight is appreciably different from that of artificial light such as tungsten illumination. The former contains comparatively equal proportions of radiations of the various wavelengths of the visible spectrum, while tungsten lighting is comparatively poor in blue and violet rays and correspondingly richer in orange to red (and infra-red) radiation.

This difference naturally also affects the speed of the various kinds of sensitive material. Owing to the low blue content of tungsten illumination the effective speed of a non-colour

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

sensitized emulsion may be one-half or even less of the effective daylight speed. A normal ortho emulsion may also lose one-third to one-half of its daylight speed when exposed by tungsten lighting.

Many manufacturers quote a separate speed figure for tungsten illumination with their materials. The standards for emulsion speed measurement lay down only one way of determining the speed figure, using a light source approximating daylight in quality. Tungsten speed figures are therefore only an approximate indication of how the material is likely to behave.

With panchromatic emulsions the value of a tungsten speed figure is doubtful, since it depends also on the method of exposure determination employed. Thus some film makers list panchromatic materials with a tungsten speed the same as their daylight speed, while others quote tungsten figures of about 30 per cent below the daylight speeds. Where an exposure meter is used for measuring the lighting level it is best, for accurate exposure determination, to find the effective film speed by a series of test exposures with that meter under the required lighting conditions.

Gradation and Contrast. Negative materials may differ from each other in respect of contrast and gradation. These two terms are commonly used synonymously and, though always associated in one way in practice, are quite distinct in theory. Contrast is the slope of the characteristic curve—that is, the rate at which density changes with exposure (or, properly, its logarithm). With a material of high contrast a small increase in exposure will produce a large increase in density and vice versa. In addition to this, however, the total exposure range covered by the useful portion of the characteristic curve is also a practically important property of any material. It determines the total brightness scale—that is, tone range or subject contrast—which the material can faithfully reproduce. Strictly, the term gradation should refer to this property.

With actual materials, high contrast is always associated with a small useful exposure range or a short scale of gradation; low contrast with a long scale of gradation. Moreover, both properties are associated with emulsion speed: slow emulsions tend to yield high contrast (hard emulsions) and to have a short exposure range: fast emulsions tend to yield low contrast (being soft-working) and a long exposure range.

These associations depend upon the fundamental properties of the silver halide crystals (large crystals being more light sensitive than small ones), upon the processes used in emulsion manufacture, and upon the properties necessary if emulsions are to be useful in practice.

Slow, very contrasty materials are used in photomechanical reproduction and for copying line originals where the only tones present are black and white. Similarly, though less extremely slow and contrasty, materials are used for rendering the low-contrast subjects frequently found in astronomy, photomicrography, etc. Fairly high contrast is also needed in copying continuous tone originals, in aerial photography, and in many technical and scientific applications.

The sensitive materials employed in everyday general and commercial photography are mostly of medium contrast.

Low contrast is an undesirable characteristic in any sensitive material. It is never welcome for its own sake, but where extreme speed is important, some lowering of contrast must be accepted.

Gradation and Exposure Latitude. The emulsions of most medium-speed to fast materials can reproduce a tone range, or subject brightness scale, much greater than that of most normal subjects. The exposure times given in the camera may therefore in many cases be increased by several hundred per cent above the minimum without the exposure given to any part of the image exceeding that which the emulsion can reproduce. This is the exposure latitude.

The permissible latitude therefore depends upon the tone range of the subject and upon the gradation (useful exposure range) of the emulsion. The more contrasty the subject, and/or the less the useful exposure range of the emulsion, the less the latitude. For the same reason, and quite apart from the emulsion speed demanded, it is essential to use fast materials—that is, those which have associated with their speed a long useful exposure range—when the subject contrast is high.

The exposure range, and therefore the latitude, of comparatively contrasty materials can

GRADATION AND EXPOSURE LATITUDE. Top: *Soft-gradation emulsion (long tone scale) can accommodate subject with great latitude.* Bottom: *Contrasty (short tone scale) material has little or no latitude and needs exact exposure.*

be increased by double coating with two emulsions—a fast and a slow layer.

Contrast Variation. Although the contrast of the developed image depends primarily on the emulsion, it can be influenced by other factors.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The most important of these is the developer and development time used. Some developer formulae inherently give higher contrast than others; and with any developer, increasing the development time increases the contrast up to a certain maximum.

Contrast also varies with the colour of the light. With panchromatic materials, sensitive to all colours, it is generally lower for blue than for red or reddish light. Hence a negative made through a blue filter has, other things being equal, a lower contrast than one made through a red filter.

This has to be taken into account when making colour separation negatives in colour photography. In practice the difference may be adjusted by giving the blue-filtered negatives longer development than the others. But there are also special materials which allow all three separation negatives to be developed for the same length of time to give images of equal contrast.

The contrast range of an emulsion may also change when the intensity of the exposing light is very high or very low (e.g., when pictures are taken by high speed electronic flash).

Graininess. The developed photographic image is not continuous; it consists of small particles of opaque, black silver, embedded in the gelatin layer. These particles become visible when the negative is greatly magnified. The tones no longer appear smooth and homogeneous, they look broken up and grainy. This graininess may show up unpleasantly in enlarged prints.

How far a negative may be enlarged before the grain becomes objectionable depends first of all on the size of the original silver halide crystals in the emulsion. The original size of the grains varies from one type and make of sensitive material to another, so the graininess of the image depends on the choice of sensitive material, among other things. A number of secondary factors also affect the grain size—e.g., the developer used, negative exposure and contrast, printing illumination and print surface.

Graininess and Speed. There is no regular connexion between the size of the silver halide crystal and the amount of light that it takes to make it developable. A large crystal generally needs no more light than a small one. So the larger the crystals, the more image silver is produced by the same amount of exposure; i.e., in effect the larger crystals tend to be more sensitive than the small ones. It follows that the coarse grained emulsions tend to be fast, and the fine grained materials slow.

The emulsions used in normal photography vary from medium to fairly fine grain. The choice of material is often a compromise between a number of factors, among which speed and grain figure largely. Miniature camera photography in particular calls for the finer grain types of film, because the negatives have to be enlarged on a proportionately bigger scale.

FILM CHARACTERISTICS. Top row: *Speed.* Second row: *Contrast; tends to decrease with faster films.* Third row: *Grain; tends to increase with speed.* Bottom row: *Resolving power; is generally higher with slower emulsions.*

Special fine grain negative materials are manufactured for photomicrography, microcopying, and spectrography, all of which call for an unusually high standard of resolution.

Completely grainless emulsions which are slower even than contact papers are used for radiography, for making graticules, and wherever the resolving power must be as fine as possible.

Resolving Power. The resolving power of a photographic emulsion is its ability to separate small image detail. It is governed by the thickness and turbidity of the emulsion and by its graininess.

The effective resolution of the image also depends on a number of other factors apart from the sensitive material, such as subject contrast, exposure, the developer and technique of development, and the resolving power of the optical system.

The relative resolving power of sensitive materials is measured by photographing a test chart consisting of sets of lines spaced at varying distances apart under controlled conditions of illumination, exposure, and development. The resolving power of the emulsion is expressed as the greatest number of lines per millimetre that can be distinctly seen (under suitable magnification) on the negative of the test chart. This figure, of course, represents the maximum number of lines that the emulsion is able to resolve under ideal conditions of testing.

A photographic emulsion of silver halide and gelatin is a turbid medium, so it tends to scatter light that passes through it. As a result,

CC-0. Jamnigh Digital Presevation Foundation, Chandigarh

RESOLVING POWER AND THE EMULSION. Left: *Resolving power depends appreciably on the grain size of the negative material. With coarse-grained emulsions the image grain may hide the finest detail.* Centre: *In a thick emulsion the image may spread owing to irradiation and in extreme cases may obliterate the smallest image detail altogether. A thin emulsion layer thus increases resolving power.* Right: *In the same way surface development which confines the image to the surface of the emulsion layer, improves effective resolution as if the emulsion itself were thinly coated.*

the silver image spreads outside the limits of the optical image. The more turbid and the thicker the emulsion, the more the light spreads and destroys the definition of fine detail. This results in lowered resolving power.

Over-exposure increases the amount of scattered light that registers on the sensitive emulsion, and also increases the depth of the image in the emulsion layer, with a corresponding loss of resolving power in each case. Over-development of the negative material destroys resolution by emphasizing the light scatter and coarsening the image.

The greater the emulsion grain, the lower the resolving power. This explains why the fast double-coated materials used in general photography have a comparatively low resolving power. The slower, fine grain emulsions have much higher resolving power. Special thin emulsions are used to give the necessary high resolving power for such work as aerial photography, photomicrography and spectrography.

For very high resolution—e.g., as in making graticules—Lippmann type plates are used. These have a very thin and almost grainless emulsion layer which is practically transparent. The silver halide content of the emulsion is comparatively low, so that such materials are often slower than the slowest lantern plates or contact papers.

Contrast Transfer Function and Acutance. In practice it is not only the resolving power that is important, but also the contrast of fine image detail. This affects the visual sharpness of an image quite apart from its resolution. Thus it is possible to have a film of high resolving power but low detail contrast, yielding an image which appears less sharp than one obtained on a film of lower resolving power but high contrast.

A more complete specification of the film performance in respect of image detail is therefore given by the so-called contrast transfer function. This is a curve which plots the resolving power against the image contrast. A practical significance of the transfer function is that it permits the selection of a sensitive material for any specific purpose, taking into account the degree of practical resolution required. Thus where it is important to resolve very fine detail irrespective of the contrast performance, a film of high resolving power at low contrast is necessary. On the other hand where extreme fine detail is less important, a film of higher contrast in the low resolution range of the transfer function is the better choice.

Another measure of the sharpness of the image obtainable on the film is the acutance. This is a physical measure of the transition across an image boundary between a light and a dark area. The steeper this transition, the sharper such an outline appears. This property is also known as the edge contrast or outline contrast of the image. It is not directly related to the resolving power; it is possible to have a low resolution film of high acutance and vice versa. Generally thin emulsion films yield images of the highest acutance.

Development Characteristics. The characteristics of a negative material must always be considered in conjunction with the developer that is to be used with it. So for any sensitive material it is necessary to know something about its actual rate of development; its potential maximum contrast; and the effect of developers on its effective speed. All these factors depend on the developer as much as on the negative material.

The rate of development in a particular developer is often highest for the slower sensitive materials; the fastest panchromatic materials generally require the longest development times. Special fast-developing high-speed films and plates are, however, manufactured for press photography and other work where rapid processing is required.

While the relative image contrast (gamma)

CONTRAST TRANSFER UNCTION. Instead of specifying the resolving power as such, the transfer function plots resolution against image contrast and so gives a more comprehensive picture of the performance of the material. The solid curve represents an ideal material; in practice the best emulsions still fall rather below that (dotted curve).

TYPES OF NEGATIVE MATERIAL

Slow	4–12	8–12	P	h.	mf.	I	Scientific
Process	—	—	P	h.	mf. or f.	S	Special copying techniques

Speed: Where no speeds are given, exposures are determined by tests for the particular set-up in use—e.g., with process materials. The materials are arranged approximately in descending order of speed. Gradation: S—soft; m—medium; h—hard; eh—extra hard; uh—ultra-hard; Grain: n—normal; mf—medium fine; f—fine; ef—extra fine; uf—ultra-fine or grainless. Availability: P—plates; S—sheet film; R—roll film; M—35 mm. miniature film; Pp—paper. Development Speed: I—very rapid; II—rapid; III—average; IV—slow; V—very slow; S—material requiring special developers and/or development procedure.

This list does not cover a large number of scientific materials for specific purposes which are made to special order only.

CC-0. Adamjidam Digital Preservation Foundation, Chandigarh

depends largely on the developer and development time, the maximum contrast (gamma infinity) obtainable in a given developer depends on the inherent gradation of the negative material.

Development in many fine grain developers lowers the effective emulsion speed of the material. Most fine grain developers lower the effective speed of the faster materials more than they do the slow. This difference is very marked with some ultra-fine grain developers. Many ultra-fine grain developers in fact offer little or no advantage with most types of high-speed materials over, say, ordinary fine grain developers with medium speed materials.

Physical Characteristics. The thickness of the emulsion coating varies according to the purpose of the material. Thick emulsions contain more silver salts than thin, so they are capable of yielding a greater maximum density, but their resolving power is correspondingly lowered. Very thin emulsions are used for work calling for the maximum amount of resolution—e.g., for fine line reproduction and making graticules.

Certain negative materials are prepared in such a way that the emulsion can be stripped off the support and, if necessary, transferred to another. These usually have a hardened emulsion coated on top of a layer of clear, unhardened gelatin. The soft gelatin makes it easy to strip the emulsion off its support. In addition, the emulsion may have a supercoat of adhesive to allow it to be transferred and stuck to another support. Such materials are known as transfer materials.

The material may also be given a final protective coating of clear unsensitized gelatin, known as a supercoat. This layer protects the sensitized emulsion from physical injury—e.g., scratching and abrasion—which tends to produce dark stress marks in the developed emulsion, even though the material itself is not visibly marked. In transfer materials, the supercoat may consist of a layer of adhesive to attach the emulsion to its new support.

Double-coated Emulsions. Many sensitive materials—particularly films for the popular photographic market—have two emulsion layers: a slow one coated directly on the support, and a fast one coated on top of the slow emulsion.

During exposure the fast emulsion layer is affected first. Further exposure affects the lower layer and forms a latent image there, so increasing the effective tone range of the material.

Double-coated materials are particularly suitable for general amateur photography because of their wide exposure latitude. Their main disadvantage is that double coating increases the thickness of the emulsion layer and gives rise to increased irradiation, so that double-coated materials have a comparatively low resolving power.

Supports. The base on which the emulsion is coated is mostly either a glass plate or a flexible film of cellulose acetate or other plastic. Glass plates are used for accurate work such as photogrammetry where dimensional stability is important, but special transparent plastic bases have been developed which are almost as stable as glass in this respect.

In addition to these transparent bases, several opaque materials are used as supports for negative emulsions. These include card (for the cheap sensitized material known as negative card), paper (for cheap paper roll films), and sheet metal (for templates).

Most negative materials are treated with some form of backing or sub-coating of dye or pigment to absorb the light scattered within the emulsion layer and reflected from the base.

Roll films and cut films are also coated with a gelatin backing to counteract the tendency of this type of support to curl in towards the emulsion layer. The anti-halo dye or pigment is usually put in this anti-curl coating. L.A.M.

NEGATIVE-POSITIVE VIEWER. Viewing system that permits a negative to be observed as a positive image (and vice versa). Viewers of this kind rely either on fluorescence quenching by infra-red radiation, or on electronic reversal of an image on a television screen.

See also: *Viewers.*

NEGATIVES FROM COLOUR SLIDES. It is often useful to be able to make black-and-white prints from colour transparencies. Since the transparency is a positive it is first necessary to make an ordinary monochrome negative from it; this negative is then used to make the black-and-white print (or a monochrome slide).

The kind of negative to be made depends upon the original transparency and the sort of print required. There are negatives—e.g., 35 mm. and other miniature sizes—made by contact printing, from which prints are made in the enlarger; small negatives made by projection—e.g., to 2¼ ins. square and 2¼ × 3¼ ins.—from miniature transparencies, to print by contact or projection; and enlarged negatives from which prints are made by contact.

Contact Negatives. These are best made on to a medium speed panchromatic film; 35 mm. films are printed in a 35 mm. printer of the type used for making film strips or miniature slides.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The disadvantage of the method is that it is difficult to prevent dust and scratches from being reproduced on the negative. These blemishes are subsequently magnified if the final prints are made by enlargement.

Contact prints from roll film transparencies —i.e., 2¼ × 2¼ ins. or 2¼ × 3¼ ins.—are made in the same way as lantern slides but on medium speed panchromatic film or plates instead of lantern plates.

Negatives by Projection. It is sometimes more convenient to make enlarged negatives from 35 mm. transparencies; the conventional lantern slide sizes are easier to handle and retouch than miniature slides made by contact. In this case the colour transparency is held in the negative carrier of the enlarger. The negative is then made by normal enlarging technique on to a suitable plate or section of film held in a frame on the enlarger baseboard.

Because the sensitive material is so much faster than bromide paper, every trace of stray light must be cut out and all operations conducted by the correct type of safelight.

If enlargements are made from negatives projected in this way, there is a further loss of definition that does not occur in the first method described, but greater freedom from mechanical defects.

Where large black-and-white prints, all of the same size, are required, an economical method may be to make an enlarged negative from which full size contact prints can be run off. Compared with the other methods, this way is too expensive in negative material to be used for making only two or three prints of one size.

Whenever the copy negative is to be printed by contact, the fact that it will be reversed from left to right must be allowed for by reversing the colour transparency in the enlarger. This enables the negative to be printed with the emulsion in contact with the printing paper. The precaution is unnecessary with negatives for enlarging because they can be reversed without affecting the definition of the prints.

Sensitized Material. The copy negative should generally be made on panchromatic material, although orthochromatic and non-colour sensitive material may be quite suitable for certain subjects just as it is in making monochrome negatives direct from the original subject. In the same way, filters may be used over the printing light to vary the relative brilliance of the colours, or to correct the colour temperature of the light source.

Medium speed material is essential to give fine grain in negatives that have to be considerably enlarged. For negatives for contact printing, faster pan films of lower contrast may be used with advantage.

The contrast of most colour transparencies is appreciable, so the film must be developed in a soft-working solution and processed to give a soft negative. The correct method is best found empirically. Any normal negative developer at half the usual strength can be used, and a few test exposures at various development times will soon give an acceptable and workable level of contrast.

Printing Light. The colour temperature of the printing light influences the tones of the negative. Tungsten lighting, for instance, being rich in red rays, will tend to lighten the tone of red and yellow objects and darken the tone of blue. This effect can be corrected by the use of a green-blue, half-watt-to-daylight correction filter in front of the lamp. Mercury vapour lighting, being very rich in blue and ultra-violet, lightens blue tones and darkens red. The spectrum of cold cathode lighting is very similar to that of daylight.

The foregoing comments apply to the making of positive prints from reversal colour transparencies; photographers who expect to require many monochrome prints may prefer to use one of the colour negative systems.

It should also be borne in mind that reversal papers are on the market which enable positives to be made without an intermediate negative. C.D.M.

NÈGRE, CHARLES, 1820–79. French painter and photographer. Began to calotype *c.* 1850, opened a portrait studio in Paris, but is chiefly known for architectural and genre photographs. Founder member of the Société Française de Photographie. Improved various photomechanical processes by which he obtained excellent half-tone pictures: heliogravure, 1854, collotype, 1856, and photogalvanography, 1861.

NEO-COCCINE. Red dye used in negative retouching. It stains the gelatin and prevents some of the actinic light from passing through and affecting the printing paper. A faint, even tint can thus be given to thin parts of the negative to prevent them from printing too dark during enlarging.

NEON LAMP. Glass bulb filled with neon gas at very low pressure and having two electrodes connected to a conventional type of cap. When the lamp is on, the gas between the electrodes glows with a pinkish light.

Lamps of this type are not bright enough for normal lighting, but they have a number of specialized uses.

Because the current consumption is very low, the light is practically cold, and there is no filament to break or burn out. Neon lamps are used as pilot lights, indicators, warning lamps and in situations where absolute reliability is essential and low current consumption is an advantage.

Because the light "strikes" as soon as the voltage is applied, and goes out immediately without any afterglow on switching off, neon lamps are ideal for use in stroboscopes.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

The neon arc strikes as soon as the applied voltage exceeds roughly 80 volts. This property is made use of in electronic timers. In these instruments the neon lamp operates a switch and breaks the enlarger lamp circuit. It does this when the voltage of an associated bank of condensers rises to a particular value; this charging period corresponds to the desired exposure time.

NEWMAN, ARTHUR SAMUEL, 1862–1943. English engineer, designer of photographic and cinematographic apparatus. Devised in 1889 his first diaphragm shutter; in 1890 the Celeritas shutter (with Simpson's of Clerkenwell, London). Manufactured with the firms of Newman and Guardia (till 1908) and Newman and Sinclair several cameras, e.g., the Standard, Nydia, Sybil, Centum (100 exposures on unperforated 35 mm. film), N & S Reflex camera. Made early cine apparatus for Friese-Greene, the Viventoscope projector for Blair (1897), supplied films and gave cine shows. In 1909 advocated standardization of motion picture films. In 1911 made the first N & S cine camera and later the clockwork Auto Kine camera. He worked as consultant for photographic and cine companies. A founder member of the British Kinematograph Society. Received the Progress Medal of the Royal Photographic Society in 1936. The Newman Lecture and Plaque were established in his memory.

NEWS PHOTOGRAPHY. Section of press photography concerned with taking pictures of topical events.

NEWTON'S RINGS. Concentric bands of coloured light sometimes seen around the areas where two transparent surfaces are not quite in contact. The rings are the result of interference and occur when the separation between the surfaces is of the same order as the wavelength of light.

In enlarging, Newton's rings can form between the surface of the negative and the glass negative carrier plate, when they produce alternate light and dark bands on the print. The cure, if the negative size is small enough to permit it, is to use a glassless carrier. With larger negatives a mask around the edge, sufficient to take the negative (usually the back) out of contact with the glass, will often put things right. In extreme cases, the negative may be pressed on to a pool of glycerine on the glass so that all air bubbles are excluded. A print made in this way will show no sign of rings. Newton's rings are more likely to occur with negatives which are not completely dry, or under conditions of high humidity.

Newton's rings can also be a nuisance in film slide projection when they form between the shiny side of the film and the cover glass in contact with it. It is difficult—and often impossible—to get rid of Newton's rings between glass-to-glass or glass-to-film surfaces. But if one of the glass surfaces is lightly etched with acid to give a fine matt texture the trouble cannot occur. Glasses treated in this way are available for mounting transparencies and also for glass negative carriers. Although it is only necessary to use treated glass for one half of the sandwich, in practice both halves are treated so that it does not matter if the glasses are interchanged. The grain of the etching is so fine that it does not show itself either on the projected image or the print.

The appearance of Newton's rings between two flat or curved glass surfaces is used as a check for flatness or regularity of curvature in fitting and inspecting optical components.

NEW ZEALAND. The photographic history of New Zealand has been much affected by its geography. Although only a small country, with a population of under three million, it spreads over a distance of about 1,100 miles from north to south. Difficulty of access resulted in there being at least two independent pioneering photographic groups in the nineteenth century. The two oldest towns, photographically speaking, are Auckland and Dunedin. Dunedin, well towards the south, was founded by Scots, whereas Englishmen were the main settlers in Auckland.

Old records show that in 1898 the Auckland Photo Club, as it was then called, was already holding annual exhibitions and the President of the club was the then Governor of New Zealand, Lord Onslow. This Vice-Regal patronage has continued—in fact, within the last year the Auckland Photographic Society, which started as the Auckland Photo Club, has won the Cup, donated by another Governor General.

The Dunedin Photographic Society's recorded history pre-dates that of the Auckland Society's earliest records and it is therefore safe to say that there was in New Zealand by 1960—only twenty years after the country became a Crown Colony—a well-established photographic group of both professional and amateur photographers. It is interesting to note that the professionals and amateurs have worked together in harmony in the photographic societies, clubs and groups in New Zealand throughout the photographic history of the country.

By 1860 there was at least one photographic retailer, Mr. H. Holland, in Victoria Street, Auckland, and Waterworths, another early dealer, was in business prior to 1880. A third name mentioned in early records is Harringtons.

Photography had an early influence on the paintings of a well-known New Zealand

painter, Goldie. Many of his paintings were done on a sensitized base, and this undoubtedly accounts for many of his astonishingly accurate portraits of famous Maori chieftains.

During the past thirty years the Auckland Public Library has collected and filed old photographs of early Auckland. This service, has helped greatly in establishing the accuracy of historical comments.

By 1913 Sucklings had purchased a large shop in Queen Street, Auckland's main thoroughfare. Sucklings offered a four-hour developing and printing service for roll films and plates. This, perhaps more than anything else, helped to popularize the idea of amateur photography in New Zealand, and when Kodak (N.Z.) Limited, was established in the early 1920's, taking over Suckling's shop in Queen Street, New Zealand photography could be said to have come of age.

In a recent survey it was estimated that the average New Zealand home has three cameras, one of which is 35 mm. There is a movie camera in every tenth home and a projector of one type or another in every eighth home. (In spite of the of the fact that the importation of cameras into the country is subject to Government control.)

Industry. In recent years almost all of the major photographic companies in the world have established representatives in New Zealand, and several manufacturers have opened colour film processing laboratories.

At the present time New Zealand manufactures 16 mm. sound projectors, 35 mm. slide projectors in two types, some twenty or thirty types of screen, simple hand illuminating viewers, slide boxes in a multitude of types, but no cameras.

New Zealand can service almost any camera, and there is available a wide range of brands of film, black-and-white, colour negative and colour reversal and most of these can be processed in New Zealand.

Societies and Clubs. Because of the difficult terrain that separates the principal cities in New Zealand, it was not until around the late 1930's that there was much direct communication between all the main centres. Now, with better roads and a good air service, New Zealanders are extremely travel-conscious, and this has led in 1954 to the establishment of the Photographic Society of New Zealand. Initially a gathering of camera clubs who came together to advance photography as an art, it has now been extended to include over 100 clubs. The Society has succeeded in welding together the clubs throughout the length and breadth of New Zealand. It holds an annual conference and it publishes its own magazine *New Zealand Camera.*

At about the same time, the professional photographers in New Zealand established the Professional Photographers' Association, which has groups for dealers, commercial and portrait photographers, etc. Members do their utmost to maintain standards of ethics and work quality; they run schools and lecture programmes and there is hardly a professional photographer in New Zealand who is not a member.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Publications. Apart from *New Zealand Camera,* there is a bi-monthly trade journal *New Zealand Studio.*

A number of the individual camera clubs publish their own journal.

There have been numerous publications of photographs, mainly in colour, of the impressive New Zealand scene. One of these, prepared by Ken Bigwood, is a two-volume publication called *Pictorial New Zealand.* Another, entitled *New Zealand Birds,* by Geoff. Moon, A.R.P.S. shows the native bird life.

Schools. Although there are night school courses and apprenticeship systems, New Zealand has no examinations or accepted professional standards. An amateur can learn from the clubs and societies, or can enrol for one of the two- or three-year courses conducted one night a week at various colleges by many of the country's leading photographers, but these vary greatly in coverage and standards. On the commercial side there is also no training programme. The Professional Photographers' Association is trying to standardize procedure, and it may not be long before recognized photographic courses will be available through the technical colleges.

Application. New Zealand photographers are employed in hospitals, universities and government organizations, particularly in the Department of Scientific and Industrial Research. Many of these have done original scientific work in the photographic field. A camera recently produced by Mr. S. Rumsey of the Dominion Physical Laboratory in Wellington is designed to take a picture of the visible sky, all at one time. The lens of this camera, which is of Mr. Rumsey's own design, is considered by many to be a major break-through in this specialized field.

In the field of medical photography, New Zealand has established a reputation for its visual training systems, usually with colour slides, which are used in training doctors and nurses, and also in the recording of certain heart and lung operations—in some cases the first of their kind in the world.

Photography is being increasingly used by industry. Many firms microfilm their documents, and a photographic record of company and product progress is common. Larger organizations publish illustrated house magazines.

New Zealand, as a small country, has always lacked capital investment, and often it has been left to the government to pioneer certain aspects of photographic work. The New Zealand National Film Unit, for example, has for many years been producing top quality films, and has won a number of awards for its productions.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

This is a field where private enterprise has difficulty in competing.

The government also maintains a large publicity department where advertising for the tourist trade is created. R.A.H.

NICKEL NITRATE. Used in certain toners.

Formula and molecular weight: $Ni(NO_3)_2 \cdot 6H_2O$; 291.

Characteristics: Green hygroscopic salt.

Solubility: About 50 parts in 100 parts of water at room temperature.

NIÉPCE DE ST. VICTOR, CLAUDE FÉLIX ABEL, 1805–70. French cavalry officer and inventor of the albumen-on-glass process, 1847. Modified the heliograph (bitumen process) of his cousin Nicéphore Niépce into a heliogravure photomechanical printing process on bitumen-coated steel plates which gave good half-tone prints, 1855. Following Edmond Becquerel's ideas Niépce de St. Victor succeeded by about 1860 in taking natural colour photographs (called heliochromy) on silver plates by the interference method. They could not be fixed and could only be viewed in dim light. Gabriel Lippmann solved the problem in 1891. Biography by R. Colson (Paris 1898).

NIÉPCE, ISIDORE, 1805–68. French, son of Joseph Nicéphore Niépce whom Isidore succeeded (1833) in the partnership with Daguerre. Does not appear to have made any important scientific or technical contribution to the further work of Daguerre, but took part in the commercial exploitation of the Niépce-Daguerre inventions. In 1839 obtained a pension from the French Government for the disclosure of the daguerreotype and heliographic processes. Published a brochure against Daguerre, 1841.

NIÉPCE, JOSEPH NICÉPHORE, 1765–1833. French amateur scientist. Invented photography in the camera, and heliogravure, both of which he called heliography. Experimented with lithography and tried to produce paper images and the printing blocks (on stone, metals, glass) by copying drawings through the action of light and subsequent etching. Used a camera (with lens) as early as 1816, and also contact copying without a camera. In 1816 obtained negatives by the action of light on paper (imbibed with silver chloride), but could only partially fix them. After experimenting with a number of substances, achieved satisfactory results by coating a pewter plate with bitumen, exposing it (by contact, or for hours in a camera), washing away with lavender oil and petroleum the shadow portions which had not been hardened by light, and thus obtaining a permanent, direct-positive picture. He was the first to use an iris diaphragm and bellows in his cameras. 1822 is probably the year in which he obtained the first successful, permanent image by contact copying; the first surviving photograph from nature, taken in a camera, dates probably from 1826. Niépce used in 1829 silvered metal plates for his bitumen photographs and darkened the shadows (bare silver) by iodine fumes; this method was described in detail in his supplement to the partnership agreement which he concluded with Daguerre in 1829, and doubtless contributed to Daguerre's discovery of the light sensitivity of iodized silver plates (1831). Niépce's contact with Daguerre had been established in 1826 through the Parisian optician, Charles Chevalier, from whom both bought lenses and optical apparatus.

The subsequent history of the Niépce-Daguerre invention will be found in the biographical notice on Daguerre. Niépce died in 1833, and his son Isidore became Daguerre's partner. Biographies by Fouque (Paris 1867) and H. & A. Gernsheim (London 1956).

NIGHT PHOTOGRAPHY

Photography in one way or another can still be carried on out of doors after the sun has set, by the afterglow in the sky in the period of dusk, by existing street, shop-window, or floodlighting, and by moonlight. The photographer can supplement these effects to a greater or less extent by adding lighting of his own—generally flash.

Equipment. The camera, its accessories, and a firm tripod form the principal items of equipment. There is one important addition that does not usually form part of a photographer's kit—a pocket torch.

There are some after-sunset pictures that can be taken with any camera and others that call for something special. If the lighting is so feeble that the photograph needs a time exposure, with the camera mounted on a tripod or other support, then one camera is as good as another. Night scenes were photographed in this way as early as the beginning of the century with lenses and sensitized materials that were impossibly slow by modern standards. So for time exposures, even a box camera will serve; the quality of the results being as good as its simple lens and limited adjustments will

permit. The subject in all such cases must of course be still.

Moving subjects call for a lens with an aperture of $f3{\cdot}5$ or preferably $f2{\cdot}0$ with accurate focusing and a shutter giving automatic exposures down to half a second. With such subjects it is not essential for the camera to be on a tripod, but some form of support is usually desirable. This is the field of the miniature camera and, in fact, the advent of this type of instrument, together with modern high-speed panchromatic emulsion, was directly responsible for the popularity of night photography.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Whatever the camera, it must have a large, clear viewfinder, plainly marked scales, and a deep lens hood. Automatic film transport is a desirable feature as it is difficult to see film numbering at night. A bloomed lens is an advantage when there are artificial lights facing the camera.

Lighting. Apart from photographs taken by dusk, moonlight, or lightning, all photography at night relies on the presence of some form of artificial lighting. This may consist of isolated street lamps or of masses of lights in busy city centres, in arcades and fair grounds, or of the special concentrations of lights at the foot of floodlit buildings. The subject may be the pattern made by the lights themselves, or an illuminated scene in which the light sources may or may not appear.

Contrast. In every case, the special character of the illumination has to be considered and, in the main, this means its peculiarity of falling off abruptly at a short distance away from the source. This is the result of the operation of the inverse square law. Artificial lighting indoors is either concentrated by reflectors or so much of it is reflected back on to the subject by walls and ceiling that the law applies only in a very modified fashion. But outdoor lighting usually radiates in all directions and is not often reflected back in useful amounts by light surfaces nearby. So the intensity of outdoor lighting at, say 20 feet from the source is only quarter the intensity at 10 feet, at 30 feet it is one-ninth, at 40 feet it is one-sixteenth and so on.

The consequence is that the picture tends to concentrate itself into localized pools of light immediately surrounding the source, with featureless areas of black in between. This is not what the eye, with its tremendous range of sensitivities, sees when it looks at the same scene. So the picture is apt to be disappointing and not at all what the photographer hoped to get when he made the exposure.

There are several things that can be done to improve the picture. The first is to choose scenes in which there are light-reflecting surfaces—buildings, foliage and flowers, even vehicles—to make the most of what light there is in the faintly illuminated areas. Secondly, the highlights in the picture can be doubled by choosing a rainy night—preferably just after a shower—when they are reflected in the wet pavement. It is often possible to make use of the surface of a river or lake in the same way, while snow-covered ground and light dusty road surfaces are equally helpful.

The violent contrasts of the scene can be reduced still further by keeping the light source out of the picture. This can often be done by choosing a viewpoint where the sources lie outside the field of the lens. Another solution is to choose a position where a foreground object—e.g., the trunk of a tree or a lamp-post—comes between the light source and the camera. This trick is particularly effective when the obstruction has a recognizable shape—e.g., a piece of statuary or even a human figure.

It also helps to use a low-contrast, sensitized material—i.e., one of soft gradation. This point is generally taken care of automatically, since the night photographer almost always uses fast panchromatic materials which tend in any case to have a soft gradation.

For the same reason, exposure should be on the generous side to get the maximum shadow detail, and development can safely be cut by 25 per cent to prevent the highlights from blocking up.

Using Flash. When flash is used out of doors at night there are no light surroundings, like ceilings and walls, to act as reflectors and throw indirect light back on to the subject and its setting. So flashlight in the open falls off rapidly and illuminates nothing beyond the actual subject. (It also illuminates any foreground objects very brightly so that they can quite easily steal the picture.)

This characteristic offers a valuable means of completely isolating a particular subject. Anything photographed in this way prints out against a solid black background. If the background and setting are necessary, the easiest way to handle the problem is to shoot around dusk, when there is just enough sky light remaining to record the setting while the shutter is open for the flash. Usually, the best way to do this is to light the subject by open flash technique and leave the shutter open long enough to give the required exposure to the landscape. Many novel effects can be created by this method of combining flash and evening light.

Halation. When the light sources appear in the picture, they are bound to show some sign of halation. This causes the image of the source itself to spread, and surrounds it with a halo of scattered light. As a rule, the longer the exposure and development, the worse the halation. It is also worse with unbacked materials, but nowadays any plate or film likely to be used for night photography is backed or treated against halation by the manufacturer.

Halation can be avoided by cutting out the light source, or it can be kept to a minimum by giving no more exposure or development than

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is absolutely necessary. Development in a surface developer is also an excellent way of avoiding halation. Finally, it can be lessened by rubbing down the affected areas of the negative with a fine abrasive paste like Baskett's reducer. But it must be remembered that a trace of halation adds a natural radiance to the light sources that can be most effective.

Flare. Most lenses produce some form of flare, but there is generally some position of the source where flare is avoidable. These positions can be found by setting up a candle or lighted torch bulb in a darkroom, focusing the lens on it, and noting the effect of shifting the image about on the focusing screen. Any serious flare noted can be avoided by keeping the light source away from the corresponding position of the test light in the picture area.

The position of a flare patch on the focusing screen of a twin lens reflex is no indication that the taking lens will form a similar patch on the negative. Flare in most lenses is generally worst at small apertures. Coating a lens reduces the likelihood of flare; any photographer who intends to take up night photography can always have the lens of his camera coated reasonably cheaply if it is not coated already.

Focusing. At night it is difficult to focus by any of the regular methods, because the subject is too dim to be seen in a focusing screen or a rangefinder field, and the light sources are too intense. The camera can be focused on a torch held near the subject; another method is to measure or pace out the distance, or, if necessary, estimate it. Slight errors in focusing are in any case less noticeable in a night photograph. As a rough rule the lens should be focused on a point about one-third of the way from the front edge of the depth of the field to be covered sharply, but it is easier to turn it right to the infinity stop for scenes where the interest lies beyond about 50 feet.

Exposure. There is no single correct exposure for any night subject; everything depends on what the final print has to show. The minimum exposure that will register the light sources would be adequate where the picture consisted of a pattern of lights only, but as soon as the negative must include an image of objects or scenery illuminated by the light source, then it becomes necessary to give a longer exposure. And the longer the exposure, the more of the scene will appear in the final print.

At the same time, there is no point in giving such a lengthy exposure that the details of the subject will be as plain as in a daylight photograph, because without some proportion of completely black shadow the photograph would lose the essential after-dark atmosphere. So the best exposure will generally lie somewhere between the above extremes. In practice this allows a great deal of latitude which is extended still further at the printing stage. By choosing a hard or soft paper, the amount of shadow detail in the final print can be widely controlled.

All that can be said about exposure is that it should be based on a selective exposure meter reading, interpreted in the light of experience and experiment and study of data published with night photographs taken under similar conditions. A rough starting point is indicated for each of the various classes of subject that are dealt with below.

Most night pictures are time exposures made with the camera mounted on a steady support or a tripod. In addition to the usual precautions taken to ensure that the camera does not move during the exposure, a special technique is necessary if there are passers-by or lighted vehicles moving in front of the camera. A piece of black card is held in front of the lens while the interruption is going on and removed as soon as it is over. This procedure can be repeated ad lib., so long as a check is kept to see that the total time for which the lens is uncovered adds up to the required exposure. However, people walking fairly quickly across the picture can be neglected; they will not affect the image.

Sensitized Materials. Since even the brightest of night scenes is dull compared with daylight, only the fastest panchromatic materials can be considered. Even for time exposures it is better to use fast panchromatic materials for the sake of their softer gradation.

Often the fastest materials are still not fast enough—particularly for use in a camera with an *f* 4·5 or smaller lens. At such times it is worth-while hypersensitizing the film or plate. This can be done either before or after exposure. There are various methods of hypersensitizing which can be expected to double or treble the speed of the material for a few days at least.

Processing and Printing. As the subject contrasts are generally too extreme to be recorded by the film, development should aim at low contrast—e.g., by curtailing the development time up to 25 per cent, by employing two bath or water bath development, or (preferably) by developing in a compensating fine-grain formula. Fireworks and similar light trace patterns, however, are rendered best by development in an ordinary M.Q. developer to get extra contrast.

The typical night photograph is best printed on a fairly hard grade of paper to bring out the shadow detail and to also reproduce good quality blacks.

Landscapes. The best time for taking open scenery and panoramas is immediately after the sun has set, and as soon as the buildings and streets are lighted up. At such times there is still enough sky light left to show up silhouettes of buildings and the line of the horizon, while lighted windows and street lamps stand out against an inky-black background.

Open landscapes with plenty of lighted roads and buildings—or even public illuminations—make excellent pictures taken in this way. Sometimes a better result is achieved by

making two exposures, one just after the sun has set, and another very much later, when all the lights have been switched on. The camera must of course be left untouched on the tripod between exposures.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The exposure for the landscape immediately after sunset should be 4–8 seconds at *f* 8 on fast panchromatic film. If a second exposure is given later to get more lights in the picture, the same exposure should be given.

Streets. In the older parts of most towns there are lamplit street corners, archways, flights of steps and alleys that make excellent picture material. Generally all that is needed is a suitable figure either under the lamp or silhouetted against its light and the result is an atmospheric picture that can be taken even with a box camera. If the light is reflected in a wet pavement, so much the better. Exposure will be anything from 5–10 minutes at *f* 11.

Street scenes in the busier part of the town call for instantaneous exposures to arrest movement. Fortunately the lighting is more powerful in such places and, by shooting when the subject is well within the full brilliance of the lamp, exposures as short as 1/25 at *f* 3·5 will give a reasonable image. At this speed the movement should be towards or away from the camera. By taking the moving figures in silhouette against a brightly lighted surface, or against lights reflected in a wet pavement, even higher speeds may be used.

Many of the latest types of mercury or sodium vapour street lamps enable much shorter exposures than this to be given, particularly if the subject or group is standing directly under the lamp and silhouetted against pavement reflections from other lights. A single figure can be very effectively photographed looking at a newspaper under the street light, because the newspaper acts as a light reflector to improve the illumination of the face.

Shop Windows. Lighted shop windows give an opportunity for two types of picture: the display figures and window-dressing arrangements and people looking at the window.

(1) As the lighting is all directed away from the observer, there is no danger of flare or halation and the results are usually excellent. One or two window shoppers silhouetted against the light help to make things more interesting. Exposures will depend on the number and power of the lamps (which vary widely) and a photo-electric meter reading is the only answer.

(2) A camera station well to the side is necessary to show the faces of the spectators as well as something of what they are looking at. This gives the photographer a chance to steady the camera against the side of the building and take a time exposure. As the faces are lit only by reflected light, the exposure must be as long as can be given without showing movement. Since the subjects are interested in what they are looking at, it is often possible to give an exposure as long as 5 seconds, but even at 1 second the result may be satisfactory.

Busy Centres. Every city has its Piccadilly Circus where there is a general blaze of light from street lamps, lighted shop windows, advertising signs and the like. Here there are interesting groups of people, newspaper and flower sellers, traffic and lively action. The possible subjects are endless and the light is generally strong enough to make snapshooting possible. Even so, the longest practicable exposure should always be given at the greatest stop that will give the required depth of field: A tripod will be out of the question, but there is never any shortage of lamp-posts, pillar boxes etc., to serve as a camera rest.

For general views of the centre, it is a good idea to shoot when traffic is stationary, just as the traffic lights are changing over. This is the right time also to catch pedestrians waiting to cross and who are generally standing under the brightest illumination.

Normal shots around centres of this type should be given an exposure of 1/10 second at *f* 2, but by carefully timing the instant of exposure it is possible to get pictures which show little movement at ½ second at *f* 4·5.

A novel type of picture results from stopping down the lens and giving a long time exposure during which the lights of moving vehicles register as parallel streaks of light. For this type of shot the camera should be on a tripod and if possible looking down on the centre.

Fairs and Markets. Pictures around fairs at night call for a variety of techniques because the subjects and lighting vary so widely. Generally speaking, there is not much point in trying to get pictures in the poorly lighted spots. The fun of the fair is in its life and action, and there are usually a number of vantage points around the more elaborate mechanical entertainments where the lighting is bright enough for instantaneous exposures. Here, the technique recommended for busy city centres will apply and exposures will be about the same.

Brightly lighted stalls like shooting galleries, houp-la, and coconut shies can be tackled like shop windows—i.e., showing the spectators silhouetted against the brightly lighted background of prizes, or shooting from the side to catch their expressions. Markets with their stalls, cheap-jacks and their audiences can be dealt with in the same way.

One great advantage of the individual lighting in such places is that, by taking a little trouble over the viewpoint, it is generally possible to isolate the subject completely against a dark background.

Finally, the long exposure technique applied to roundabouts, switch-backs or the Big Wheel will often yield delightful light-trace patterns if the shutter is left open for one or more revolutions.

Floodlit Buildings. These are ideal subjects for simple cameras, since they can be given a long

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

time exposure without any fear of movement. The building should first be studied from every angle to find the most effective viewpoint—it is rarely the flatly-lighted view from straight in front that shows the subject to the best advantage. With a camera that has no rising front movement it will usually be necessary to choose a distant viewpoint to keep the tilt of the camera as small as possible. At the same time, a violent tilt from a close-up viewpoint may be effective.

The subject should be framed if possible—e.g., by shooting from between trees or foliage, or the bold shapes of other buildings—to give a feeling of depth and distance. A foreground figure silhouetted against the light is an alternative device for imparting space.

Exposures with this type of subject vary with the intensity of the floodlighting and the colour of the building. Average conditions call for about one second at *f*8 for white lighting; when the lighting is coloured, it is generally weaker, and will require up to four times the white light exposure.

Colour. It is possible to make colour pictures of after-dark scenes which include artificial lighting, but it is difficult or impossible to get the colour values exact. If the lighting is a mixture—as it usually is—of tungsten, fluorescent and gas discharge light sources, no single type of colour film can reproduce them all faithfully at one and the same time. The result, whether you use colour film corrected for artificial or daylight, is bound to be a compromise. This does not always mean that the result will be unpleasant, but it will not be an exact reproduction of the colours of each light source.

The problem is worse when there is still some daylight left in the sky and you want to reproduce it as well as the street lighting, advertising signs, lighted house and shop windows and so on. A professional photographer will generally use artificial light material and concentrate on getting good, clear colours in the man-made lighting. Amateurs usually want to shoot only one or two frames on this kind of subject and are not prepared to load up with an A-type colour film when the greater part of it would be wasted. Those who shoot off a few night exposures on a daylight colour film must put up with a certain amount of colour distortion, however carefully they gauge the exposure.

The extreme lighting contrast of night photographs also means that the dark parts of the picture are invariably underexposed—they are, after all, night. Similarly, light sources in the picture are over-exposed, While this does not necessarily detract from the pictorial effect, it does mean that on colour film a certain amount of distortion of the shadow and brightest tones occurs. With long exposure times, reciprocity failure effects lead to further colour changes. In practice, the results are usually still acceptable, especially as few people can accurately remember—or even reliably see—the colour values in a dimly lit scene.

Paradoxically, accurate exposure in night photographs is not so critical, because the exposure level mainly affects the degree of gloom or brightness in the final colour transparency. Accordingly, the effects obtained vary with the exposure, but the result is an authentic night shot over a surprising range of exposure levels. Without this pseudo-latitude successful night photography would be impossible.

Rain. Taking photographs in the rain at night is an unpleasant procedure, but it is always worth while going out with a camera immediately after a shower when the wet pavements and roads reflect all the lights of street lamps, shop windows, advertising signs and so on. The pavement reflections also form a bright background to figures and objects that would otherwise be lost. The extra reflected light enables exposures for most subjects to be cut by about a half.

Snow. A covering of snow is an even better reflector which also adds a touch of novelty to the most ordinary scene. Powerful lights near the camera should be avoided as they will create a glare in the foreground that nothing else in the picture will be able to compete with. Shooting during a snow-fall gives the picture a misty, soft-focus appearance.

Exposures can be cut to half the normal value or even less.

The use of a lens hood is desirable to protect the lens against falling snow.

Mist and Fog. Both these conditions affect the subject in the same way: they obliterate distant lights and put a luminous halo around the ones nearer the camera. So they tend to isolate and simplify the subject and lend it an atmosphere of mystery or unreality. Here again, a well-placed figure can often have a dramatic impact.

There is no need to increase the normal exposure—in fact, particularly in mist, it may be possible to reduce it. This is because the mist acts as a reflector and actually increases the illumination of the shadows. F.P.

NITRAPHOT. Slightly over-run type of tungsten filament lamp. Similar to a large size (No.2) over-run Photoflood but having a longer working life.

See also: *Filament lamps.*

NITRATE FILM. Standard 35 mm. commercial cine film which used to be coated on a base of cellulose nitrate. It is no longer used because it was highly inflammable.

See also: *Supports for emulsions.*

NITRIC ACID. Aqua fortis. Used in dish cleaners, and is the etching mordant for zinc and magnesium in photomechanical work.

Formula and molecular weight: HNO_3; 63.

Characteristics: Highly corrosive yellowish liquid (colourless if pure).

Solubility: Mixes with water in all proportions.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

NODAL POINT. A ray of light enters a lens at a definite angle with the optical axis and leaves the lens also at an angle with the axis which is, in general, different from the first. However, sometimes the angle for the entering ray is equal to that of the emergent ray. For this condition the position where the entering ray would cut the optical axis is called the first nodal point, and the position on the axis from which the emergent ray appears to come is called the second nodal point.

In general when there is the same medium on both sides of the lens, usually air, the nodal points are where the principal planes cross the axis; but in cases when there are different media surrounding the lens, as in an oil-immersion microscope objective or the human eye, the nodal points are not in the principal planes of the lens.

NOISE POWER SPECTRUM. The fluctuations in a photographic image which are due to granularity may be represented by a density distribution with the characteristics of a random waveform. Fourier analysis of this waveform into spatial frequency components leads to the noise power spectrum. This term originates from the field of electrical communications, and the name *Wiener* spectrum is sometimes alternatively used.

NORWAY. Norway has not contributed to the invention and development of photography, nor has the country any photographic industry. The population is only 3 millions and the basis for such an industry would be too small to be firmly established.

The Past. The first daguerreotypes made in Norway date from 1842—three years after Daguerre made his invention public. It is known that in 1842 a daguerreotypist named Knudsen settled in Oslo, the capital of Norway (then Kristiania). From 1843 there are daguerreotypes from Bergen signed Iversen, and these two may be considered as Norway's first portrait daguerreotypists. These was also a calotype portrait photographer, H. T. Winther, who opened a studio in Oslo in 1842.

The most prominent portrait photographers using the wet plate process were L. Szacinski and O. Nyblin of Oslo (Kristiania). The former, who was an immigrant Pole, was also by appointment photographer to the Royal Court.

Amateur photography has developed greatly during the last decades. The first known amateur photographer was the clergyman, Ole Tobias Olsen, who became interested in photography early in the 1860's. He used a wet plate camera of considerable weight and size, and with this equipment he made several thousand photographs of various parts of Norway. Most of these are of historical interest and are housed in the Norwegian Technical Museum at Oslo, where his photographic equipment may also be seen including his darkroom tent and complete wet plate outfit. Bearing in mind that Norway—although beautiful—is very mountainous and difficult to penetrate, especially when there were no railways, no automobiles and very poor roads, Ole Tobias Olsen's performance is unique not only from a photographic point of view, but also as an athletic achievement.

The first amateur club, Amatørfotografen (The Amateur Photographers), was founded in Oslo in 1888 and lasted until 1907. The members used mostly dry plates. It numbered about 100–150 members, the best known being Frithjof Nansen, the Norwegian polar explorer and scientist, in later years famous for his international work for the refugees after the first World War on behalf of the League of Nations.

Present-day Activities. In 1921 a new amateur club was founded, named Kristiania Kamera Klub (now Oslo Kamera Klub). Membership has grown from 100–150 to over 700. In 1927 this club together with two other clubs, Rjukan Kamera Klub and Fredrikstad Kamera Klub, founded the Norsk Selskap for Fotografi (Norwegian Photographic Society) which is the central organization of Norwegian camera clubs.

The number of clubs is now seventy-seven and the total membership about 4,000. The Norsk Selskap for Fotografi publishes the journal *Kamera*, and arranges yearly photographic competitions. The N.S.F. is a member of F.I.A.P. and of P.S.A.

The professional photographers in Norway are organized in Norges Fotografforbund (The Norwegian Photographers' Association) founded in 1894, now numbering about 300 members. Their official publication is the *Norsk Fotografisk Tidsskrift.*

Photography is not introduced as a subject in any of the high schools or universities of Norway, but the university of Oslo has a laboratory for photographic research. Photographic education is included as a special subject in the Craftsman Schools (for apprentices) at Oslo and Trondheim and the Arts and Crafts School at Oslo. Moreover, members of the Norges Fotografforbund lecture on photography, especially to candidates to the Master Craftsman Certificate.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Pictorial photography, which has developed considerably in recent years in Norway, is following the general world trend. Norwegian photographers are active in international exhibitions and competitions. The country's largest camera club, the Oslo Kamera Klubb, celebrated its fortieth anniversary in 1961 by holding an international exhibition in the Museum of Applied Art in Oslo. R.Mo.

NOTCH. Sheet film is notched to ensure loading the material into the film holder with the emulsion facing the right way. When the notch is at the top left-hand side of the sheet, the emulsion side is facing away. Various shapes of notching indicate different types of emulsion.

NUCLEAR PHYSICS. The photographic detection of atomic particles, such as electrons, protons, alpha particles, neutrons, mesons and others has greatly contributed to our fundamental knowledge in atomic and nuclear physics. With nuclear track plates it is possible to trace the paths of fast charged particles, when these travel through the photographic emulsion. They leave rows of developed silver grains, i.e. tracks in the layer which can be identified under microscopic inspection.

History. O. Mügge (1909) was the first who observed charged particle tracks in photographic emulsions and Kinoshita (1910) working in Rutherford's laboratory made systematic studies of the photographic recording of alpha particle tracks. M. Blau and H. Wambacher (1920–1930) investigated the use of photographic emulsions for protons and for nuclear disintegrations. The climax of this development was reached when in 1945–9 C. F. Powell and his collaborators in Bristol refined the technique by using a new type of nuclear track plate supplied by the photographic manufacturers and discovered the existence of pi-and mu-mesons. Powell received the Nobel prize for this work.

Types of Elementary Particles. A proton is the nucleus of the hydrogen atom with a positive charge of unity.

An electron has a negative charge with a mass 1840 times smaller than that of the proton.

A neutron has no charge and is one of the building stones of the nuclei of atoms. It has practically the same mass as the proton.

The alpha particle with its double positive charge is the nucleus of the helium atom; it has 4 times the mass of a proton.

Mesons are also elementary particles and there exist 11 varieties of them; these differ in mass, charge and some are uncharged. They have masses 200–1000 times that of the electron. Mesons are believed to be responsible for the exchange interactions between protons and neutrons in the atomic nucleus.

When a fast charged particle passes through the silver bromide grains of a photographic emulsion it loses energy by the ionization it causes within the grains. The nature of the tracks depends on the number of ionizations the particle causes per unit length of path. The rate of production of ions by a particle is proportional to the square of its charge and inversely proportional to the square of its velocity. Hence a heavy particle of a given energy; for example an alpha particle with its double charge and its relatively low speed because of its great mass, produces so many ionizations that it renders all grains developable along its path. A proton of the same energy has a higher velocity because of its smaller mass and leaves a few gaps between the developable grains in its initial path. Towards the end of the trail, when the proton is slowing down the grain density increases. Hence different particles may be distinguished by the change in grain density per unit length of path. Furthermore the discrimination is often facilitated by the amount of scattering a particle suffers due to interactions with atoms through which it passes.

A neutron, having no charge, causes no ionizations and leaves no tracks in the emulsion. If it collides, however, with a hydrogen nucleus in the gelatine of the emulsion, this may take up the energy of the neutron and from the lengths of the proton tracks thus obtained, conclusions can be drawn as to the energies of the colliding neutrons.

Nuclear Track Plates. One of the outstanding properties of nuclear track plates is their proportion of silver bromide to gelatin which is much higher than in normal emulsions. Hence the grains are very closely packed, thus permitting the formation of continuous rows of grains. In order to record the full range of particles, emulsion coatings may be up to 1 mm. thick. As very high energy particles may have ranges of the order of several centimeters in the emulsion stacks of plates may be superimposed. Such stacks of up to 50 cm. thickness have been carried in balloons in tests reaching an altitude of 100,000 feet. In this experiment 300 kg. of silver bromide emulsion was used and 20 tons of hypo was required for the fixing of the emulsion.

Processing. The processing of nuclear track plates having emulsion thicknesses up to 50–100 microns is almost conventional apart from slightly increased bathing times. Usually metolhydroquinone developers are used.

For plates of 200, 600 and 1000 microns, the so-called temperature cycle method is used. The plates are soaked in the developer solution at 5°C. so that the developer can diffuse to the depth of the layer without acting on the latent image. The temperature is then raised to about 25°C. and development takes place simultaneously throughout. The soaking and development time may, depending on emulsion

thickness, take up to 10 hours; the fixing time 100 hours and washing including drying 10 days. A 1000-micron thick emulsion layer thus requires about a fortnight for its complete processing.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Inspection. For the detailed inspection of tracks formed in the emulsion high power microscopes with oil immersion objectives are required. In order to obtain a pictorial record of three-dimensional nuclear events a great number of photo-micrographs have to be made at different focusing levels and several hundreds may be required for one event. Finally the various photomicrographs are arranged in a mosaic.

Cloud-, Bubble- and Spark Chambers. Other detectors of charged particles which use photographic recording methods are the well established Wilson cloud chambers. In these the particles leave a visible track of condensed droplets in passing through super saturated water vapour. The trail of drops is photographed by synchronized electronic flash with a stereoscopic camera.

More recently huge and very powerful detection instruments have been developed such as the bubble and the spark chambers. In the former liquid hydrogen or propane is used at a temperature above the normal boiling point of the liquid, but boiling is prevented by applying a high pressure. This is reduced for a short time so that the liquid remains super-heated. If a charged particle passes through the super-heated liquid it causes a local heating along its path thus forming visible bubbles for a few milliseconds. These can be photographed by illuminating the bubbles in a dark field. In one investigation 50,000–100,000 pictures may be needed with two cameras to select and reconstruct nuclear events in space.

In the spark chamber the track of a pre-selected particle reveals itself as a train of sparks caused by an electrical breakdown between plates. This is triggered by the ionizing particle.

Spark track photographs can be taken from mirrors set at 45- which allow a three-dimentional reconstruction of the event.

Autoradiography. The photographic emulsion, e.g. fast X-ray film, is often an alternative choice to the use of Geiger counters particularly when very weak radioactive samples have to be measured and when many samples have to be measured simultaneously. R.H.H.

NUDE PHOTOGRAPHY

In photographing the nude there are two particular difficulties to overcome: one, the naked presence of human body and the built in realism of the photographic process. The mechanical aspect of photography contrasts strongly with all the other graphic arts and the basic manual skills they involve. For this reason, at earlier periods, attempts were made to suppress blatant reality via various special printing processes such as bromoil, bromoil transfer, pigment ana gum bichromate, and the like. Although perfectly valid in their own way, these processes led to increasingly laboured and unsatisfactory imitations of Romantic or impressionist painting, purely to escape the lens's "reality", not only in the hazardous field of nude photography, but also in many others.

The lens of course "sees" objectively. The essence of the camera and at the same time its most obvious application is the straightforward record. The lens registers everything before it indiscriminately. The human eye, however, is different. It corrects and selects according to requirement, even governing its own exposure. It freely appraises and arranges, in an effort to bring the elements of choice, emphasis and suppression to the various parts of the scene.

The close relationship between eye and lens reveals the futility of borrowing techniques from the other graphic arts. Through this partnership of precise optical reproduction and human selectivity, still photography and, in particular, the cinema have become a peculiarly typical medium of expression of our time. In the hands of the talented, the camera becomes an integral part of life, portraying facts in detail but colouring them with vision. Yet the understanding of its operational intricacies is far from simple, requiring much ability, taste and discrimination, and in no sphere of photography is this more true than in nude photography.

Nude photographs have a right to existence and publication only if they satisfy basic aesthetic and pictorial requirements. For this reason they are considered difficult even from a professional point of view. The photographer himself therefore has to be his own best critic, and uncompromising in his attitude to everything which detracts from the artistic image of the picture or which could be held to be sheer eroticism.

But the nude does not need justification as it presents anyone of reasonable artistic sensibility with one of the most poetic motifs conceivable. Approached in the right spirit and with developed critical judgment, the nude should create no more problems than any other photographic field.

Equipment. Formerly there was no question that the best negative size for nude photography was also the biggest. Even today the professional who still prefers the large-format camera for studio work has every reason for his choice. The big ground-glass allows easy control of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

detail. The resulting contact prints or colour transparencies require the minimum extra work for reproduction purposes. Furthermore, modern cameras of the large-format type have become handier and more streamlined, and weight and size are no longer serious obstacles for their hand-held use in fields demanding more mobility.

Many specialists in nude photography prefer the 2¼ × 2¼ ins. twin- or single-lens reflex camera. The construction of these cameras requires the square negative for optimum use of the design's potential, and this apparent necessity in fact proves in many ways a virtue. The square format is adaptable and permits the choice of vertical or horizontal arrangements at will. The negative is big enough to allow sectional enlargements to be made from it without noticeable loss of quality, yet at the same time the camera is compact and simple in operation. Composition and sharp focus are facilitated by the bright ground-glass screen. The fact that the screen image is reversed from left to right is no real disadvantage, and one gets used to it very quickly in practice. If necessary, pentaprism devices are available, which will give a laterally correct, upright image. The 6 × 6 cm. reflex is in fact the ideal instrument for most general work, and the negative a good compromise between large and small.

35 mm. technique has been transformed by the arrival of ultra-fine grain, thin-emulsion films, with their excellent resolution and contour sharpness. Their appearance enabled the miniature camera to compete on far more favourable terms with larger cameras, while retaining its own special advantages. The changes brought about were even more widespread than those heralded by the earlier introduction of fast emulsions, and affected the development of nearly all black-and-white films in all sizes. It is, however, a paradox that the thin-emulsion film provided some of the best-known photographers of the "nouvelle vogue" with an excuse for expressing their "disgust at so much sharpness" and producing pictures, among them nudes, in which graininess became a virtue.

The thin-emulsion film really comes into its own in combination with the miniature single-lens reflex, with automatic diaphragm and exposure coupling, pentaprism and instant-return mirror, an instrument which has gained tremendous popularity since the beginning of the sixties. The single-lens reflex finder has many advantages, and probably is the nearest approach to the ideal. It gives a large, bright, upright and laterally correct image, totally devoid of parallax, and showing the exact field and sharp focus of any lens without the need for an appropriate additional finder.

These developments have made the present-day 35 mm. camera almost universal in its scope. In the field of nude photography, especially by available light, its outstanding advantage lies in its ease of handling and complete mobility. But it is a precision instrument demanding a specialized and disciplined approach if above-average results are to be achieved, and slipshod work will merely produce pictures which might as well have been taken with the simplest snapshot camera. Many current 35 mm. cameras embody automatic exposure control. This is quite all right for casual record photography, but in order for it to be acceptable for serious work, there must be provision for manual operation as well.

Choice of a camera depands, of course, not only on technical specification, but also on one's own personal preference and custom. A reasonable basic outfit could consist of the following: a 35 mm. camera for available-light nudes, dynamic action, and all cases where quick shooting is necessary, using films (according to requirement) of any speed between 16 and 800 ASA; a single-lens reflex with normal, wide-angle, and medium-tele lenses would probably be ideal, and a 2¼ × 2¼ ins. twin- or single-lens reflex expressly for colour.

Materials. Present-day miniature films of medium sensitivity have a smooth gradation, and can be used for most general subjects. However, in spite of their rather steeper gradation, ultra-fine grain emulsions are to be recommended whenever the finest detail is required. These slow, contrasty films must not be overexposed, and are best if uprated to the next higher sensitivity (for example, 20 ASA becomes 40). They should be developed in energetic but soft-working developers—the very opposite of super fine-grain formulae—which give maximum emulsion speed consistent with acceptable gradation. Such developers properly used with a correctly-exposed film of the right kind will soon demonstrate their efficacy in subduing excessive contrast, grain, and blocked-up shadows. At the same time they enhance contour-sharpness and graphic effect.

In colour, reversal films are best reserved for projection. Colour prints from reversal films only give satisfactory results as a rule from transparencies of soft, even hues.

The versatile negative colour process has much to recommend it. If the user has neither the time nor the equipment to carry out the processing himself, with its rather complicated filtration steps, he would be well advised to work with a recognized processing laboratory. This is certainly not cheap, but generally results in consistent and reliable prints which in the long run save time and trouble.

Models. Finding a model can be something of a problem, but not so fraught with difficulties as one might think. Certainly no one who is really serious about nude photography will consider it impossible to solve. It should not, for example, be too difficult to persuade your wife or girl-friend to pose, and members of your own family are always potential models. If the results are good, they will probably be

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

exhibited or at least shown to friends, and this may well bring in more recruits. Before publishing any photographs, however, it is important to explain to your model exactly what you intend to do with the pictures, especially if there is a possibility of their being published. In this case the model's permission is essential (and, if she is under legal age, her parent or guardian's too), preferably in the form of a written model release.

Working with professional models is always a pleasure. Although they may not necessarily know the ultimate purpose of the photographs —something which is primarily the business of the photographer, they are quicker to grasp an idea and interpret and react to instructions, and this saves time and effort. Make-up, hairstyles and accessories are the tools of their trade, together with the ability to achieve absolute accuracy in pose and expression before the camera, the prerequisite of carefully arranged artificial-light nude work in the studio. The open air nude, on the other hand, is generally far more relaxed and unposed.

The attractiveness of a young girl often lies purely in her personal charm. This makes it difficult to set out a list of desirable attributes. Furthermore it would be folly to expect to find perfection in shoulders, arms (especially), hands, legs, breasts and back in most women. Such combination is rare, and each model usually has an imperfection of some sort.

The photographer of the nude has a more difficult task than the painter. He must be more critical of his model and more able to recognize her particularly attractive features. He cannot alter in the same way as the artist with brush or pen; he must omit, arrange, distribute, emphasize and conceal. The model's appearance as a whole is of far greater importance than minor bodily deficiencies, and she must move well. In addition, the photographer needs at least an element of psychological skill in his directing ability.

The Nude Out of Doors. Nudity in a photograph must have a *raison d'être*. It must not contradict its surroundings. The most convincing, and perhaps the simplest, setting is out of doors. Today, as a reflection of human longing for fresh air, space, and sunshine, naturist camps and reservations have grown in popularity and number, and have made the notion of open air nudity readily acceptable.

To photograph your model in motion, you can simply allow her to wander about at will, while you follow her movements with the camera and expose at the right moment. But there is a likelihood that this will result in perhaps one breathtaking success along with thirty-five mediocre shots, which would strain even the most dynamic concept of miniature technique. So it is much better to keep everything under your control. The best kind of directing is an almost impreceptible prompting, so that the model herself does not know the precise instant of each shot. You can suggest she runs into the water or over the sand dunes. Directing need not be complicated, but it must be there, and the photographer should dictate the right moment rather than leave it to chance. The results should still be totally spontaneous.

In summer the most favourable time for photography is up to 11 o'clock in the morning and between 4 and 6 o'clock in the afternoon. Slanting rays of sunlight have a charm all of their own, which is equally valid for black-and-white and for colour film, with which the lower colour temperature gives a pleasantly warm cast. Strong sidelight is particularly effective with nudes, giving simple modelling to the lines of arms or hips, or delineating the thrust of shapely breasts. Lightening the shadows is mostly superfluous with black and white, but necessary for colour.

Working against the light usually guarantees striking effects in black-and-white, and also in colour photography, provided that measures are taken to brighten the shadows via white reflectors or fill-in flash. The against-the-light technique adds brilliance to almost any picture, with gleaming highlights side by side with dark shadows, and, in the case of nude photography, the naked form acquires an embracing luminosity. Strong contrasts and deep shadows appear, and the elements of the picture gain unity. When backlighting comes from water, it creates reflections all round the model.

Backlighting is also the most effective form of lighting when the nude figure is to be an integral part of a landscape. Precise exposure is essential. The old rule of thumb to give three times the exposure is a guide, but may also mislead. It is essential to decide what are the most vital parts of the picture; e.g., a girl's body which must remain dark apart from backlit contours demands a different exposure from a model moving about in the sea. If you are in doubt, you should expose for the shadows, taking a close-up reading with the exposure meter, and shielding it from the direct rays of the sun. When necessary, the incident light method, as opposed to reflected, can be adopted.

Flat frontal lighting is still the safest for colour, but only used for black-and-white nude photography if particularly graphic effects are required with orange or red filters, or alternatively high-key effects in diffuse light with a blue filter.

Diffuse veiled sunlight is particularly valuable. It gives abundant illumination, especially by the sea, and when light mist or haze is present, backlit photographs taken in it acquire a beautiful luminosity. If the mist is fairly dense and a telephoto lens is used, to give a reasonably large image, the sun itself may be included in the picture. A lightly overcast sky can be ideal for certain kinds of colour work, and noticeably beneficial to skin tones. Cloudy conditions, however, are unsuitable for black-and-white, unless you are aiming at special effects, such as

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

high key, since, in the dull light will have an adverse effect on flesh tones, producing a rather ugly result.

One further vital point must be made in connection with the nude outdoors: it is essential to ensure that the model has no unsightly patches on her body caused by sunbathing in a swimsuit.

Indoors. Choice of motif is more limited in this case, but there are still many interesting possibilities, such as window lighting, bedroom and bathroom scenes, and the girl can be given something appropriate to do, such as arranging her hair in the mirror. Ordinary domestic surroundings, with tables, sideboards, armchairs etc. are but rarely happy choices; the nude in these surroundings looks quite out of place or even an object of ridicule. But the inspired photographer may be able to use even such unlikely contrasts for surrealist effects.

Large rolls of white or grey paper may be hung on the wall of a room to make a neutral background. A tripod is absolutely necessary, and any difficulties are likely to involve lighting.

Contrasts between the area of the window and the dark parts of the room are always considerable, unless a daylight studio with lighting from three sides and above is available. These contrasts need to be reduced, and the best method is the old professional trick of using reflecting screens and folding sheets of aluminium foil which can be moved about until the desired amount of fill-in illumination is achieved. Aluminium sheets throw a rather metallic gleam on the skin. Carefully controlled, this gleam is generally desirable, especially with slightly oily skin. If this is better avoided, however, particularly for colour work, large sheets of matt white paper or linen are preferable.

Artificial Light. The composed nude photograph almost invariably requires artificial light. The most usual and convenient form of illumination is obtained from Photoflood lamps. They are inexpensive and easy to control and position. Basic equipment for the average amateur studio might consist of the following; one general-purpose floodlamp, one diffused flood, and one spotlight. However, it is quite possible to make do with the diffused flood and the spotlight alone. Each must be mounted on its own movable stand. A considerable amount can be achieved with such a simple set-up.

BASIC LIGHTING SCHEME. A, model. B, diffused flood lamp for fill-in lighting. C, flood lamp on background. D, camera. E, spot lamp for key lighting.

In positioning the lights, the photographer should bear in mind that there is nothing to be gained by using more than necessary. In fact, where two lights are enough, a third may well spoil the effect. But the third light can prove particularly useful for illuminating the background.

Both main lights should be kept fairly well back from the model, and they should never compete with each other. The principal illumination must come from one direction to give modelling, while the other lamp lightens the shadows.

As with natural light, aluminium foil sheets can often be used to good effect.

Background. In all indoor work the line formed at the angle of floor and wall can prove a nuisance. The problem can be solved with a roll of white or grey background paper roughly 6 yards long and 3 or 4 yards wide. This is hung from the wall in a gentle curve to the floor, and the model stands, sits or lies on one end. It can be illuminated according to taste, and forms what is known as a seamless background.

Colour film calls for fine pastel skin tones. Often, however, skin tones can be far from perfect in actual fact. A half-stop extra exposure will make them paler and more idealized. A good compromise is to use the half-stop extra with reflected illumination from light neutral grey paper, which will counteract any tendency for the colours to get too washed out. It is essential, of course, to see that the colour temperature of the lighting is correct for the film in use.

Flash. Electronic flash and bulbs can be used to give direct frontal light from the camera position, and this can prove reasonably satisfactory with colour. With black-and-white, however, it is better to have camera and flash apparatus separated by one or more extension cables or even slave units. Extension cables should preferably not exceed 9 feet in length. The flash is then virtually independent of the camera and much the same rules apply as for lighting with photofloods.

The simplest standard flash lighting for nudes is from above and to one side. The flashgun can either be mounted on a stand or an assistant can hold it.

Bounce flash is excellent for soft, even lighting. The flashgun is pointed up at an angle to the ceiling (which must be white or light-coloured), and the exposure increased by one to two and a half stops. A certain amount of trial and error may be necessary. This kind of illumination is virtually shadowless, and ideal for high-key work. It may be found worthwhile

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

BOUNCE FLASH ARRANGEMENT. A, *bounce flash reflected from ceiling on to model.* B, *flash off the camera for key lighting.* C, *paper roll background.*

to supplement it, however, with direct light from a second flash head.

Here again the exposure must be found by experience.

A disadvantage with flash work is that it is difficult to judge the final effect of the lighting, although some idea may be gained by using tungsten lighting to simulate the flash. Therefore there are certain types of nude shot which suggest themselves more readily for flash, such as the model under a shower or in a foam or sauna bath. The short duration of electronic flash will freeze any movement and the light itself gives a good rendering of wet skin, while the inherent nature of the subject promises spontaneity.

It is possible to use mixed flash and tungsten illumination for black-and-white work, but it is more difficult with colour, because of the different colour temperatures of the two forms of lighting. Colour conversion filters (on the lights) and considerable experimenting may be necessary.

Flash is useful as a fill-in light out of doors for against-the-light shots. The brilliance of the flash must be reduced, however, either by varying the flash-to-subject distance or by using a handkerchief or similar cloth in front of the reflector, otherwise the picture will look completely unnatural because of the predominance of frontal lighting. H.R

O

OBERNETTER, JOHANN BAPTIST, 1840–87. German photographer and photographic manufacturer. Introduced commercially, 1868, under the name of Aristotypie the collodion silver chloride paper of G. W. Simpson, and invented *c.* 1886 a photogravure process on copper plates called Lichtkupferdruck. Obernetter also introduced *c.* 1870 a collotype process similar to Josef Albert's. In the 1880s his firm made good orthochromatic dry plates.

OBJECTIVE. Lens, in an optical instrument, that normally faces the object. More often applied to the lenses of telescopes and microscopes than cameras.

OCUP, PETER ADOLFOVICH, 1883–1963. Russian press photographer and Master of Photographic Art. Established a portrait gallery of famous writers and artists, including Tolstoi, Chekhov and Gorkij. Made photographic documentation of Russo-Japanese War 1904–5, and of the Revolution. Took a series of portraits of Lenin, collected under the title Leniniana. Received the Order of the Red Banner of Zabour and the Order of Lenin.

OFFICE COPYING Photographic method of making same-size copies of original documents, letters, drawings, etc. There are various processes in use, utilizing either silver halide systems or electro-photographic, heat and other systems. Office copying machines are usually designed for simplest possible handling, with automatic exposure control and processing, to allow use by comparatively unskilled staff.

See also: *Document copying: Document copying equipment.*

OHM. Unit of resistance in electricity, often denoted by the symbol Ω. For convenience, other units also used are the kilohm (1,000 ohms) and the megohm (1,000,000 ohms).

See also: *Electricity.*

OIL PRINTING. Printing process introduced in 1904 in which oil pigment was applied, by brush, to a gelatin relief image.

See also: *Printing processes (obsolete).*

OIL REINFORCEMENT. Oil pigment can be used to reinforce the tones of prints on matt or rough surfaced papers. The method makes it possible to alter the tonal range of the print. Shadows can be made deeper in tone or highlights made lighter, or too insistent details suppressed. Many photographers question the use of such after-treatment on the grounds that it is not a photographic process, but for those who wish to experiment, here is the procedure:

The print must be quite dry for this work. It is laid face up on a smooth surface and the emulson side is rubbed over with print dope. This can be bought ready prepared or made up from a mixture of:

Turpentine	2 ounces	50 c.cm.
Mastic varnish	1 ounce	25 c.cm.
Linseed oil	1 ounce	25 c.cm.

The materials must be of good quality and purchased from an artists' colourman.

After the print has been treated with this medium, care being taken to go over the whole surface, the pigment can be applied in the form of good quality artists' oil colours or those supplied for the bromoil process.

The colours must harmonize with the colour of the print. Brown-black suitable for bromide prints on warm tone papers can be made by mixing black with a little burnt sienna.

A little of the pigment is squeezed from the tube on a sheet of clean glass and mixed with a small quantity of the medium. The mixing is done with the flat blade of a knife and care taken not to have the colour too strong.

A plug of cotton wool is rubbed into the mixture and lightly rubbed on to the print to apply the colour as evenly as possible. A second piece of clean cotton wool is then used to work the colour well into the print, and to remove any surplus.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The colour should be even; if there are patches of uneven density or colour the whole will have to be wiped off with cotton wool saturated with the medium or pure turpentine, and a fresh start made.

Any modification of the print may then be proceeded with. Using a tuft of cotton wool lightly moistened with the medium, the highlights that are to be reduced are wiped over. Any points of light, such as shafts of sunshine or the catch lights in the eyes of a portrait, are brightened up with cotton wool wrapped round the point of a small stick. Cloud form can be emphasized by using larger pieces of cotton wool. Any sharp outlines left can be smoothed out by gentle rubbing with clean wool. Local areas can be made darker with more pigment applied on cotton wool on a pointed stick.

R.M.F.

See also: *Doping prints; Retouching.*

ONE SHOT COLOUR CAMERA. Special type of camera used for making three-colour separation negatives with a single exposure.

See also: *Colour camera.*

OPACITY. Anything which transmits (e.g., a photographic silver deposit) 1/xth part of the light falling on it, is said to have an opacity of x. The reciprocal 1/x is called the transparency, and the logarithm log x is known as the density.

See also: *Density.*

OPAL GLASS. Glass which has a translucent opal tint throughout its thickness, as opposed to flashed opal which is opal on one surface only.

It is used as a diffuser in enlargers, photometers and other optical systems.

OPAL LAMP. Ordinary filament lamp with an opal glass bulb. When maximum diffusion is required, this bulb is better than those which are merely sprayed or frosted on one surface.

OPALOTYPE. Obsolete, once popular, type of print made by transferring a carbon process image on to translucent opal glass or by printing direct on to a bromide emulsion ready coated on opal glass. Such prints were often finished by mounting them on plush in gilt frames or with elaborate coloured borders.

See also: *Printing processes (obsolete).*

OPEN FLASH. Flash technique in which the camera shutter is held open while the flash is fired. In open flash, the duration of the exposure is governed by the burning time of the flash bulb or flash powder.

See also: *Flash synchronization.*

OPHTHALMIC PHOTOGRAPHY

Elementary ophthalmic photography is within the province of nearly every medical photographer. When the needs of the ophthalmologist alone are to be met, certain specialized cameras and apparatus rather than routine studio equipment are essential.

Choice of general equipment is largely determined by the areas to be covered which, in the main, range from head-and-shoulders to part of a single eye. By virtue of this restricted range, much useful work can be done with 35 mm. cameras and materials; many small units favour this approach since the use of monochrome and colour reversal stock almost eliminates darkroom work. The following notes apply equally to large or small negative sizes.

Success in ophthalmic photography depends upon attention to the following four points:

(1) Comfortable, but firm fixation of the head of the patient and in turn the direction of gaze of the eye. The former is achieved by a headrest; the latter by providing a fixation point—usually a small, bright, movable light.

(2) The use of intense short duration illumination (i.e., flash) to minimize discomfort, arrest movement, and permit the use of the smallest possible lens aperture. The last two features are particularly important when working at a scale of 1 : 1 or greater, as will often be the case.

(3) The control of reflections. The surface of the eye presents a wet, shiny surface which inconveniently reflects an image of any light source directed upon it or any bright object placed in its vicinity. The aim is therefore to use a single light source in dim surroundings; the size and position of the single reflex which results is carefully adjusted to avoid obscuring a point of interest.

OPHTHALMIC TABLE. Universal table for ophthalmic photography with head rest for patient and central geometric stand for positioning camera equipment.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(4) Whenever possible, photographs should be made to a definite scale, which will depend upon the area involved. Thus scale may vary from a reduction of 1 : 3 for a head and shoulders to a magnification of 3 : 1 in the case of a single eye. These figures relate to a finished print size of $4\frac{3}{4} \times 6\frac{1}{2}$ ins. which is usually adequate.

Sensitized materials employed in ophthalmic photography are strictly conventional; uses are to be found for 35 mm. colour materials. In the larger sizes medium speed orthochromatic film is recommended for general purposes, with high speed softer contrast panchromatic film on occasions.

General Technique. External photography of the patient falls broadly into the following categories, on which choice of equipment is based:

(1) Head-and-shoulders—to show general appearance, head tilt or ocular torticollis.

(2) Face only—to show distribution of lesions in relation to the eyes. Here the avoidance of distortion is of importance.

(3) Both eyes—mainly to compare one eye with another or to demonstrate a bilateral lesion in moderate detail only. This is also the standard pose for eye movement studies in which the nine positions of gaze are frequently recorded.

(4) Single eye: a close-up view of one eye only is invariably required to record adequately all but gross lesions of the external eye and anterior chamber. A magnification of at least $\times$ 2 to $\times$ 3 should be presented in the final print, and it is therefore desirable that at least half this magnification is obtained at the negative stage.

(5) Macrophotography of the eye: it will sometimes be necessary to make photographs of a portion of the eye to simulate the appearance through a low-power microscope. This is better achieved by using a short focus lens at great extension rather than through a compound microscope.

All the above work may be carried out with any camera capable of triple extension—by means of bellows or extension tubes—together with a range of lenses. For example, a 4 $\times$ 5 ins. camera should be provided with lenses of 2, 5 and 8 ins. focal length, whereas 35, 50 and 90 mm. lenses will be found most suitable for use with a 35 mm. camera.

A single lens reflex is probably ideal for these purposes, but conventional film and plate cameras will serve almost equally well. As camera requirements may be expressed in terms of a series of fixed extensions, much can be done with simple fixed-focus equipment which facilitates standardization of results.

Other necessities comprise a specially constructed table on which are mounted a head-rest for the patient at one end, and a movable geometric stand which acts as the camera support. This latter may be slid on guide rails the whole length of the table and thus, with a range of lenses, all the areas referred to above can be embraced by this excursion; the stand itself also provides fine adjustment of camera position in three planes.

Lighting. As already indicated, some form of flash illumination should be employed. As such sources are likely to be used in fairly close proximity to the eye, they must be well shielded.

A single 500 watt focusing spotlight is sufficient to provide general illumination for setting up and focusing as well as for cinematography when the use of a single light source is desirable. If electronic flash is chosen as the exposing source one flash head capable of dissipating 200 joules is essential and two may be an advantage on occasion.

Reflectors should be detachable to restrict the effective size of the light source at close quarters.

At all times the source of illumination should be kept at the greatest possible distance from the subject consistent with correct exposure at a nominal lens aperture of *f* 32. With a medium-speed orthochromatic material this distance will vary from about 3 feet for a whole head to 15 ins. for a single eye and even less for macrophotography.

Modern battery/mains operated electronic flash units having compact flash heads have sufficient light output for photography of the eye in colour, provided they are used close to the subject; moreover, their spectral emission is well matched to daylight colour film. Marked lens apertures will now range from *f* 16 to *f* 11 as the position of the light source—held, say, at the lens panel—and the degree of camera extension vary over distances from 1 to 3 feet.

Conditions more nearly approaching the desiderata outlined above may be attained by the use of expendable flash bulbs; this method is, however, relatively expensive.

Cinematography. The motion picture has a special place in ophthalmic photography. In the studio it is used for the study of eye movements, pupillometry and in the recording of such phenomena as nystagmus. In many instances use may be made of the time-compression and time-extension properties (fast and slow motion) of this medium.

In the operating theatre cinematography can record and reproduce a view of surgical procedures which is otherwise seen only by the surgeon himself.

The use of two 500 watt spotlights, each 6 feet distant, permits exposures on artificial light 16 mm. reversal colour film at 16 f.p.s. using a lens aperture of *f* 5·6. This level of illumination does not distress patient or surgeon and does not promote undue drying of exposed surfaces. For such work, the camera should be mounted about 30 ins. vertically above the face of the supine patient and roughly on a level with the chin: at this distance a 15 mm.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

lens will accept a general view and a 102 mm lens enables the frame to be filled by a single eye. Apart from these special points standard cinematographic practice is observed.

Retinography. Photography of the fundus oculi can, as yet, only be undertaken with specialized equipment such as a fundus camera. Briefly, the periphery of a large aspheric objective directs near-axial illumination through the pupil of the eye, thus illuminating a portion of the retina. The emergent rays are brought to a focus by the central portion of the objective to form an aerial image of the retina which is picked up and magnified by a small reflex camera integral with the instrument.

Light sources for this type of work have varied from the carbon arc to an incandescent lamp with an annular filament. The latest development in this respect is the use of electronic flash.

Keratography. This is a technique for producing photographs which provide information regarding the surface and curvature of the cornea. By suitable calibration of the photo-keratoscope which makes these records, the radius of curvature of different parts of the cornea may be directly measured. The method is also of value in the diagnosis of early keratoconus.

Essentially, a large illuminated target is placed a short distance in front of the eye under examination; a fixed-focus camera whose lens mount protrudes through the centre of the target, records the image of this target, which is mirrored by the cornea. The system is so arranged that when the target, which carries a geometric pattern, is at its optimum working distance the reflected image will also be in sharp focus at the film plane. Commonly the illuminated target consists of a series of concentric rings which, when reflected by a perfectly spherical surface of appropriate radius, appear to be equally spaced and uniform in thickness. In keratography, the size of the rings bears a definite relationship to the radius of curvature of the cornea and local surface irregularities are indicated by breaks in the rings or distortion of the image.

Various other experimental techniques have been tried from time to time. Stereoscopic photography, for example, has its applications and ingenious cameras have been designed for this purpose. This technique has been used to photograph the angle of the anterior chamber as seen through a gonioscope.

In gonioscopy, however, as in the recording of biomicroscopic appearances with slit-lamp illumination, the ophthalmic artist has pride of place. P.H.

OPTICAL AFTERTREATMENT. Optical methods of negative aftertreatment are used for adjusting contrast and for intensification.

Copying to Adjust Contrast. If a negative lacks contrast, one way out of the difficulty is to make a duplicate and add extra contrast in the process of duplication. The same process can be used to produce a duplicate with a lower contrast than the original if the original negative has too much contrast. This avoids ruining the negative during aftertreatment.

The duplicate negative may be made by contact printing or copying in the camera. In each case it is first used to produce a positive transparency from which the duplicate is obtained by repeating the same process.

The contrast of the original negative is decreased in the duplicate by using a soft gradation lantern plate (for contact printing) or a soft negative material in the camera (during copying). A soft working developer for the intermediate positive and/or the duplicate negative will have the same effect.

The contrast of excessively soft negatives is increased by using a hard lantern plate or process material in the camera, and/or developing in a contrast developer of the caustic hydroquinone type. This is the method often adopted for making tone separation negatives.

Copying for Intensification. Grossly underexposed negatives often have only a very faint ghost image in the shadow regions. This is much too thin either to print in the normal way or to respond to intensification.

But even a thin image shows up clearly if it is viewed against a dark or black background by oblique lighting. The visual effect of the image is considerably intensified in this way.

This effect can be utilized by copying the negative by this type of lighting. The principle of the lighting set-up is similar to that of dark ground illumination in photomicrography.

The negative to be copied is mounted in a frame with an aperture just large enough to

OPTICAL INTENSIFICATION. The negative, too thin for printing, is halogenized, and copied in front of a black background, by oblique illumination. The copy negative shows greatly improved shadow detail brought out by scattered light.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

OPTICAL INTENSIFIER LAYOUT. The negative is placed between the semi-reflecting plane surfaces of two plano-convex lenses at a small angle (a) to each other. A light beam projected through this system forms, in addition to a primary image, a series of successive images due to inter-reflection between the plane lens surfaces. These successive images largely overlap and reinforce the primary image and can, by positioning a slit, be projected on to the printing paper as an optically intensified image. The number of intensifying reflections possible is limited by the loss of definition occasioned through incomplete superimposition of the reinforcing images. A, first converging point of image beam. B, final converging point of image beam. C, screen with aperture. D, projection lens. E, printing paper. F, diaphragm in front of light source (point source). G, upper condenser lens with semi-reflecting plane surface. H, negative. J, oil bath (to eliminate additional interface reflections). K, lower condenser lens. L, movable mirror to locate any of the beam converging points in the screen aperture C.

take the negative. The frame is set up a short distance in front of a black background—e.g., a piece of black velvet, or a door opened on to a darkened room—and illuminated by a pair of spotlights, one pointing from each side of the negative and striking it at an oblique angle from the front. The camera is set up opposite the negative so that it looks through it at the black background.

Under these conditions the faint image will appear as a positive image, and straightforward copying in the camera will directly produce a duplicate negative. This negative usually shows shadow tones in sufficient strength for normal printing or enlarging.

The visual effect of the image can, if necessary, be further increased by bleaching the original negative in a halogenizing bleacher—e.g., copper sulphate. Alternatively, this optical intensification effect can be further amplified optically. This involves a fairly complex set-up of lenses and mirrors which reflect the light to and fro through the photographic image, building up an optical image of increasing contrast and density. L.A.M.

See also: *Contrast control; Duplicate negatives; Intensification; Masking.*

OPTICAL AXIS. Axis of symmetry of an optical system—e.g., of an assembly of glasses making up an objective or a projection system.

See also: *Lens.*

OPTICAL BENCH. Basic laboratory device for measuring the performance of lenses. It consists of a long wooden or metal track carrying accurately centred supports for a light source, the lens under test, and a screen on which the image of the light source formed by the lens can be examined.

The optical bench may also be used for photometry by mounting a Bunsen photometer in the centre of the bench with light sources for comparison mounted on slides at either side.

The performance and characteristics of concave mirrors may be investigated on the optical bench in the same way as lenses except that the screen on which the image is formed is on the same side of the mirror as the object (usually a fine wire grid in front of a diffused light source). In this case the screen must be shielded from the direct rays of the source so that it receives only the image forming rays from the mirror. So the screen must lie slightly to one side of, or above, the optical axis and the angle of the reflected ray must be taken into account when measuring the various separations.

These are the basic essentials, but there is provision for adding other measuring or optical equipment. The distances between all the items can be varied, without moving them off the common optical axis.

OPTICAL CALCULATIONS

The symbols used in the following equations are collected and defined as follows:

F = Focal length of a complete lens system (total focal length).

f_1 = Focal length of the first component of a two-component system.

f_2 = Focal length of the second component of a two-component system.

P = Power of a lens in diopters.

S = Axial separation between two components.

u = Conjugate distance between the front nodal point of a lens and the object (in an enlarger the object is the negative).

v = Conjugate distance between the rear nodal point of a lens and the image (in an enlarger the image is the copy board).

D = Distance between object and image ignoring nodal point separation = sum of conjugate distances = (u + v).

O = Size of object (linear).

I = Size of image (linear).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SYMBOLS AND DIMENSIONS. M = Optical magnification = $\frac{\text{size of image}}{\text{size of object}} = \frac{I}{O} = \frac{v}{u} = \frac{1}{R}$

R = Optical reduction = $\frac{\text{size of object}}{\text{size of image}} = \frac{O}{I} = \frac{u}{v} = \frac{1}{M}$

d = Effective clear diameter of a lens.

n = Relative aperture or *f*-number = $\frac{F}{d}$

c = Diameter of circle of confusion.

H = Hyperfocal distance.

L = Movement of lens system along its axis.

POSITIONS OF LENSES AND FOCAL PLANES

The fundamental equation is

$$\frac{1}{F} = \frac{1}{u} + \frac{1}{v}$$

Several rearrangements of the parent equation are possible but the following are selected as being the most convenient in use.

Focal Length. The focal length required by conditions of use can be defined in terms of any two of the following factors: object distance, image distance, magnification or reduction, sum of conjugate distances.

$$F = \frac{uv}{(u + v)} = \frac{u}{(R + 1)} = \frac{Rv}{(R + 1)}$$

$$\frac{Mu}{(M + 1)} = \frac{v}{(M + 1)} = \frac{DR}{(R + 1)^2} = \frac{DM}{(M + 1)^2}$$

Object Distance (e.g., closest distance in copying, lens negative distance in enlarging). This can be determined if two of the following factors are known: focal length, image distance, magnification or reduction, sum of the conjugate distances.

$$u = \frac{vF}{(v - F)} = F(R + 1) = \frac{F(M + 1)}{M} = \frac{DR}{(R + 1)} = \frac{D}{(M + 1)}$$

Image Distance (e.g., total camera extension in copying, lens-paper distance in enlarging). This can be determined if two of the following factors are known: focal length, object distance, magnification or reduction, sum of the conjugate distances.

$$v = \frac{uF}{(u - F)} = \frac{F(R + 1)}{R} = F(M + 1) = \frac{D}{(R + 1)} = \frac{DM}{(M + 1)}$$

Magnification or Reduction. This can be determined from two of the following factors: object distance or size, image distance or size, focal length or sum of conjugate distances:

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

$$M = \frac{I}{O} = \frac{v}{u} = \frac{(v - F)}{F} = \frac{v}{(D - v)}$$
$$= \frac{F}{(u - F)} = \frac{(D - u)}{u}$$
$$R = \frac{O}{I} = \frac{u}{v} = \frac{F}{(v - F)} = \frac{(D - v)}{v}$$
$$= \frac{(u - F)}{F} = \frac{u}{(D - u)}$$

Conjugate Sum (e.g., total height of a negative above the baseboard in an enlarger). This requires two of the following factors: focal length, object distance, image distance, magnification, or reduction.

$$D = \frac{F(M + 1)^2}{M} = \frac{F(R + 1)^2}{R} = \frac{v(M + 1)}{M}$$
$$= v(R + 1) = u(M + 1) = \frac{u(R + 1)}{R}$$
$$= u + v$$

Object Size (e.g., field size covered in close-ups or copying). This can be determined from the magnification or reduction and the image size, or from the latter with two of the following factors: image distance, object distance, sum of conjugate distances, focal length.

$$O = IR = \frac{I}{M} = \frac{IF}{(v - F)} = \frac{I(D - v)}{v}$$
$$= \frac{I(u - F)}{F} = \frac{Iu}{(D - u)} = \frac{Iu}{v}$$

Image Size (e.g., screen dimensions required in projection). This can be determined from the magnification or reduction and the object size, or the latter together with two of the following factors: image distance, object distance, sum of conjugate distances, focal length.

$$I = \frac{O}{R} = OM = \frac{Ov}{u} = \frac{O(V - F)}{F}$$
$$= \frac{Ov}{(D - v)} = \frac{OF}{(u - F)} = \frac{O(D - u)}{u}$$

Space does not permit examples for every variation of the fundamental equation but the following will indicate the manner of use.

Example 1. What focal length of lens is required to form a half-size image of an object if object-image distance is fixed at 9 ins.?

$$D = 9; R = 2$$
$$F = \frac{DR}{(R + 1)^2} = \frac{9 \times 2}{(2 + 1)^2} = \frac{18}{9} = 2 \text{ ins.}$$

Example 2. What are the conjugate distances of a 4 ins. focal length enlarging lens working at 5 times enlargement?

$$F = 4; M = 5$$
$$u = \frac{F(M + 1)}{M} = \frac{4(5 + 1)}{5} = \frac{24}{5} = 4{\cdot}8 \text{ ins.}$$
$$v = F(M + 1) = 4(5 + 1) = 24{\cdot}0 \text{ ins.}$$

Example 3. What is the focal length of a lens with conjugate distances 30 and 6 ins.?

$$u = 30; v = 6$$
$$F = \frac{uv}{(u + v)} = \frac{30 \times 6}{30 + 6} = \frac{180}{36} = 5 \text{ ins.}$$

Example 4. What is the distance between a lens and its image plane if the focal length is 20 ins. and the object 10 feet from the lens?

$$F = 20; u = 120$$
$$v = \frac{uF}{u - F} = \frac{120 \times 20}{120 - 20} = \frac{2400}{100} = 24 \text{ ins.}$$

Example 5. What is the maximum magnification possible in an enlarger with a baseboard lens distance of 36 ins. and a focal length of 4 ins.?

$$v = 36; F = 4$$
$$M = \frac{(v - F)}{F} = \frac{(36 - 4)}{4} = 8 \text{ diameters}$$

Example 6. What is the field width covered when copying with a 5 ins. lens at 30 ins. from the object, on a negative $2\frac{1}{4}$ ins. wide?

$$F = 5; u = 30; I = 2\tfrac{1}{4}$$
$$O = \frac{I(u - F)}{F} = \frac{2\frac{1}{4}(30 - 5)}{5} = 2\tfrac{1}{4} \times 5$$
$$= 11\tfrac{1}{4} \text{ ins.}$$

COMBINATIONS OF LENSES

Total Focal Length (e.g., effective focal length with a supplementary lens). The focal length of a combination of two lens components is dependent on the focal length of each component and the separation between them.

$$F = \frac{f_1 f_2}{(f_1 + f_2 - S)}$$

Focal Length of One Component. If the focal length of one component (e.g., camera lens) of a two-component system is fixed, the focal length of the other (e.g., supplementary lens) needed for a given total focal length for the combination is defined by the equations:

$$f_1 = \frac{F(f_2 - S)}{(f_2 - F)}$$
$$f_2 = \frac{F(f_1 - S)}{(f_1 - F)}$$

These focal lengths are positive when the lens is collective, and negative when dispersive.

If the focal length of one component (e.g., the supplementary lens) is known in diopters, the equation becomes:

$$f_1 = \frac{F(100/P - S)}{(100/P - F)} \text{ cm.}$$

or:

$$f_1 = \frac{F(39{\cdot}37/P - S)}{(39{\cdot}37/P - F)} \text{ ins.}$$

CC-0. Agrima Botanical Museum and Digital Preservation Foundation, Chandigarh

Axial Separation. The separation between two lens components of given focal length which will provide a given total focal length for the combination is defined by the equation:

$$S = f_1 + f_2 - \frac{f_1 f_2}{F}$$

Here again the focal lengths are positive for collective, and negative for dispersive, lenses.

If only approximate focal lengths are required in the previous equations and the two components are placed very close together (e.g., a supplementary lens mounted on a camera lens) S can be ignored, and the previous equations become:

$$F = \frac{f_1 f_2}{(f_1 + f_2)}$$

$$f_1 = \frac{F f_2}{f_2 - F}$$

and so on.

Object Distance with Supplementary Lenses. When the camera lens is focused on infinity, and a supplementary lens f_2 is added, the object distance for a sharp image becomes:

$$u = f_2$$

The distance is thus independent of f_1 or F, or S. This does not apply when the camera lens is focused on nearer objects; in that case the combination has to be calculated.

Example 7. What is the focal length of the combination of two collective lenses with focal lengths 4 ins. and 9 ins. if the separation between their nodal points is 1 in.?

$$f_1 = +4;\ f_2 = +9;\ S = 1$$

$$F = \frac{f_1 f_2}{(f_1 + f_2 - S)} = \frac{4 \times 9}{(4 + 9 - 1)} = \frac{36}{12}$$

$$= +3 \text{ ins.}$$

Example 8. What is F in example 7 if the 9 ins. lens is dispersive?

$$f_1 = +4;\ f_2 = -9;\ S = 1$$

$$F = \frac{f_1 f_2}{(f_1 + f_2 - S)} = \frac{4 \times (-9)}{(4 + (-9) - 1)}$$

$$= \frac{-36}{-6} = +6 \text{ ins.}$$

Example 9. In a telephoto system comprising a front collective lens of 5 ins. focal length and a rear dispersive lens of 6 ins. what is the separation between their nodal points to produce a 10 ins. combination?

$$f_1 = +5;\ f_2 = -6;\ F = +10$$

$$S = f_1 + f_2 - \frac{f_1 f_2}{F} = (+5) + (-6)$$

$$- \frac{5 \times (-6)}{+10} = -1 - \frac{-30}{+10} = -1 + 3$$

$$= 2 \text{ ins.}$$

Example 10. What is the maximum focal length of supplementary lens required to shorten the focal length of a 4 ins. lens so that it can focus on an object 10 ins. from the lens maintaining a camera extension or v dimension less than 5 ins.?

$$f_2 = 4;\ u = 10;\ v = 5;\ \text{assume S to be negligible}$$

$$F = \frac{uv}{(u + v)} = \frac{10 \times 5}{10 + 5} = \frac{50}{15} = 3\tfrac{1}{3} \text{ ins.}$$

$$f_1 = \frac{F(f_2 - S)}{(f_2 - F)} = \frac{3\tfrac{1}{3}(4 - 0)}{4 - 3\tfrac{1}{3}} = \frac{13\tfrac{1}{3}}{\tfrac{2}{3}} =$$

$$\frac{40}{3} \times \frac{3}{2} = 20 \text{ ins.}$$

FOCUSING MOVEMENTS

Lens Movement. The forward movement of a lens to focus sharply a near object can be defined in terms of the distance of the object and the focal length of the lens. This movement is measured from the position in which the lens focuses sharply an infinitely distant object.

Object Distance. If a lens is moved forward by a known amount from the position in which it focuses an infinitely distant object, the position of an object which will be sharply focused can be defined in terms of this movement and the focal length of the lens. In the case of cameras where object distances are intended to be measured from the focal plane instead of the node of the lens, the object distance can be denoted by the symbol Up.

When u, the object distance, is measured from the front nodal point of the lens system:

$$L = \frac{F^2}{(u - F)} = \frac{FI}{O} = \frac{Fv}{u}$$

$$\text{and } u = \frac{F(F + L)}{L}$$

When Up is measured from the focal plane:

$$L = \frac{Up - 2F - \sqrt{Up^2 - 4FUp}}{2}$$

$$\text{and } Up = \frac{(F + L)^2}{L}$$

An approximate equation which can be used for most practical purposes is:

$$L = \frac{F^2}{(Up - 2F)}$$

Magnification and Camera Extension. The maximum enlargement obtainable from a given camera extension (i.e., focusing movement in front of the infinity position) is:

$$M = \frac{L}{F}$$

Conversely, the extension required for a given magnification is:

$$L = FM$$

Example 11. In a camera where object distances are measured from the lens node, what is the focusing movement from the infinity position for a 6 ins. lens to focus at 8 feet?

$$F = 6;\ u = 96$$

$$L = \frac{F^2}{(u - F)} = \frac{6^2}{(96 - 6)} = \frac{36}{90} = 0{\cdot}4 \text{ ins.}$$

Example 12. In a camera where object distances are measured from the focal plane, what is the forward focusing movement of a 5 ins. lens to focus an object 3 feet?

$$F = 5;\ Up = 36$$

$$L = \frac{Up - 2F - \sqrt{Up^2 - 4FUp}}{2}$$

$$= \frac{36 - 10 - \sqrt{1296 - 720}}{2}$$

$$= \frac{26 - \sqrt{576}}{2}$$

$$= \frac{26 - 24}{2}$$

$$= 1 \text{ in.}$$

The approximate equation gives:

$$L = \frac{F^2}{(Up - 2F)} = \frac{25}{36 - 10} = \frac{25}{26}$$

$$= 0{\cdot}962 \text{ ins.}$$

Example 13. What is the forward focusing movement from the infinity position required for copying at a reduction of 3× (i.e., a magnification of $\frac{1}{3}$) with a 12 cm. lens?

$$F = 12;\ M = \tfrac{1}{3}$$

$$L = FM = 12 \times \tfrac{1}{3} = 4 \text{ cm.}$$

Focusing Movements with Supplementary Lenses. If the total focal length of the combination of a camera lens and a supplementary lens is computed as described in the section on Combinations of Lenses, all the equations in the other sections can be used to determine the behaviour of supplementary lenses.

Alternatively, the following simplified procedure will yield information on the focusing movements using supplementary lenses.

When a camera is focused on infinity, the distance focused on when a supplementary lens is put in front of the camera lens is equal to the focal length of the supplementary lens. This distance should be measured from the supplementary lens—strictly, from its nodal point, but the front surface is usually good enough.

The focal length in inches of a supplementary lens whose power is expressed in diopters is equivalent to 39·37 divided by the number of diopters.

Thus the distance focused on when a two-diopter positive supplementary lens is positioned in front of a camera lens focused on infinity is 39·37 ÷ 2 = 19·7 ins.

When a camera is not focused on infinity, the new object distance, Us, when using a supplementary lens can be determined if the focal length of the supplementary lens, f_2, and the focused object distance, u, of the camera lens alone is known.

Assuming negligible separation between the two lenses, the equation is:

$$Us = \frac{uf_2}{u + f_2}$$

Example 14. A camera is sharply focused on an object 5 feet from the lens. If a 1 diopter positive supplementary lens is placed in front of the camera lens, what is the new object distance which is sharply in focus?

$$u = 60;\ f_2 = 39{\cdot}37$$

$$Us = \frac{uf_2}{u + f_2} = \frac{60 \times 39{\cdot}37}{60 + 39{\cdot}37} = \frac{2362{\cdot}2}{99{\cdot}37}$$

$$= 23\tfrac{3}{4} \text{ ins.}$$

DEPTH OF FOCUS AND DEPTH OF FIELD

The numerous equations under the above heading are all based on the assumption that some degradation of definition is permissible in the recorded images of objects not sharply in focus. The criterion of permissible unsharpness is the circle of confusion.

Circle of Confusion. The diameter of the circle of confusion defines in an arbitrary manner the degradation of definition that can be accepted for a particular purpose. A perfect lens can record pin-point images of pin-point objects at the distance sharply focused upon. Point objects at other distances are recorded as circular patches, or circles of confusion, instead of true point images. In photographs to be viewed at an eye distance of about 10 ins. it is considered that circles of confusion less than ·005 in. in diameter are indistinguishable from true points. The circle of confusion which can be allowed in the negative should be chosen with respect to the degree of subsequent enlargement, if any, and to the probable viewing distance of the print. Many depth of field tables are based on the acceptance of a circle of confusion whose diameter is equivalent to the focal length of the lens divided by 1,000.

Depth of Focus. The permissible tolerances in the distance between a lens and the sensitive emulsion, i.e., depth of focus, are:

$$\text{Permissible tolerance} = cn$$

For near objects this becomes:

$$\text{Permissible tolerance} = \frac{cvn}{F} = \frac{cun}{(u - F)}$$

These tolerances for depth of focus ignore any considerations of depth of field and should therefore be reduced as much as possible.

Near and Far Limits. The size of the circle of confusion and thus the degradation of definition increases gradually as the object distance is increased or decreased from the ideal sharply focused distance. If the degree of degradation of definition that can be permitted is defined in terms of the size of the circle of confusion, the near and far limits and thus the depth of field within which the object distance may vary can be determined from equations involving knowledge of the focal length of the camera lens, the relative aperture at which it will be used, and the object distance at which it is sharply focused.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The fundamental equations for depth of field are:

$$U_1 = \text{Nearest distance in focus} = \frac{Fu(F + cn)}{(F^2 + ucn)}$$

$$U_2 = \text{Farthest distance in focus} = \frac{Fu(F - cn)}{(F^2 - ucn)}$$

Taking c as 1/1000 of the focal length, the equations become

$$U_1 = \frac{uF(1 + n/1000)}{(F + nu/1000)}$$

$$U_2 = \frac{uF(1 - n/1000)}{(F - nu/1000)}$$

Ignoring the fraction n/1000 as negligible compared with 1 further simplification gives the approximate equations:

$$U_1 = \frac{uF}{F + nu/1000}$$

$$U_2 = \frac{uF}{F - nu/1000}$$

For most practical purposes especially where u is large relative to F, depth calculations may be simplified by first computing the hyperfocal distance and proceeding from there.

Hyperfocal Distance. This is the nearest distance in focus when the lens is precisely focused for an infinitely distant object.

$$H = F + \frac{F^2}{nc}$$

$$U_1 = \text{Nearest distance in focus} = \frac{Hu}{(H + u - F)} \text{ or approx. } = \frac{Hu}{(H + u)}$$

$$U_2 = \text{Farthest distance in focus} = \frac{Hu}{(H - u - F)} \text{ or approx. } = \frac{Hu}{(H - u)}$$

If the nearest and farthest distances U_1 and U_2 are fixed then the lens must be focused on a distance u such that:

$$u = \frac{2U_1 U_2}{(U_1 + U_2)}$$

and the aperture must not be wider than

$$n = \frac{(U_2 - U_1)F^2}{2U_1 U_2 C}$$

when u is large compared with F.

Interchangeable Lenses. The simplification of the depth-of-field equation based on a circle of confusion of F/1000 is only valid for a lens of normal focal length, i.e., approximately equivalent to the image diagonal.

This condition is not fulfilled with interchangeable lenses of different focal lengths used on one and the same camera where negatives are used to about the same degree. Here calculations can conveniently be based on the equation for the hyperfocal distance:

$$H = F + F^2/nc$$

Usually F can be neglected compared with F^2/nc and H becomes proportional to F^2.

If this hyperfocal distance H_s is known for the standard focal length F_s, the value H_x for a different focal length F_x is given by:

$$H_x = H_s (F_x/F_s)^2$$

Depth of field limits for the alternative lens can then be recalculated from its hyperfocal distance.

Total Depth. When the lens is set at short copying conjugate distances the depth of field is small and it is sufficient to compute the total depth of field between the near and far limits instead of each limit separately.

$$\text{Total depth (far to near)} = (u_2 - u_1) = \frac{2cn(M+1)}{M^2} = 2cnR(R + 1)$$

Example 15. A miniature camera mounts interchangeable *f*2 lenses. What is the permissible tolerance on the distance between lens and emulsion if the circle of confusion must not exceed ·002 in.?

$$c = \cdot002;\ n = 2$$

$$\text{Tolerance} = cn = \cdot002 \times 2 = \cdot004 \text{ ins.}$$

To maintain this tolerance with any of the lenses the seating face on the camera and also the shoulders on each individual lens must be held to not more than half this, i.e., ·002 ins.

These tolerances must be reduced appreciably if the performance expected from the use of depth of field tables is to be obtained.

Example 16. What is the depth of field of a 2 ins. lens working at *f*4 and focused on an object at 3 feet (36 ins.) from the lens if the permissible circle of confusion is ·002 ins.?

$$u = 36;\ F = 2;\ n = 4;\ c = \cdot002$$

$$u_1 = \frac{Fu(F + cn)}{(F^2 + ucn)} = \frac{2 \times 36(2 + \cdot008)}{4 + \cdot288} = \frac{72 \times 2\cdot008}{4\cdot288} = \frac{144\cdot576}{4\cdot288} = 33\cdot7 \text{ ins.}$$

$$u_2 = \frac{Fu(F - cn)}{(F^2 - ucn)} = \frac{2 \times 36(2 - \cdot008)}{4 - \cdot288} = \frac{72 \times 1\cdot992}{3\cdot712} = \frac{143\cdot424}{3\cdot712} = 38.6 \text{ ins.}$$

The approximate method gives:

$$H = F + \frac{F^2}{nc} = 2 + \frac{4}{\cdot008} = 502 \text{ ins.}$$

and

$$u_1 = \frac{Hu}{(H + u)} = \frac{502 \times 36}{502 + 36} = \frac{18072}{538} = 33\cdot6 \text{ ins.}$$

$$u_2 = \frac{Hu}{(H - u)} = \frac{502 \times 36}{502 - 36} = \frac{18072}{466} = 38\cdot8 \text{ ins.}$$

Example 17. If two objects are positioned 4 feet and 5 feet from a 5 ins. lens, what object distance should be focused upon and

what is the widest relative aperture to yield a standard of definition corresponding to a circle of confusion of ·004 ins.?

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

$$u_1 = 48;\ u_2 = 60;\ F = 5;\ c = \cdot 004$$

$$u = \frac{2u_1 u_2}{(u_1 + u_2)} = \frac{2 \times 48 \times 60}{48 + 60} = \frac{5760}{108}$$

$$= 53\tfrac{1}{3} \text{ ins.}$$

and

$$n = \frac{(u_2 - u_1)F^2}{2u_1 u_2 c} = \frac{(60 - 48) \times 5^2}{2 \times 48 \times 60 \times \cdot 004}$$

$$= \frac{12 \times 25}{96 \times \cdot 24} = \frac{300}{23 \cdot 04} = f\,13$$

Example 18. How much depth of field can be expected when a lens working at $f\,4$ copies an object at half size reduction and the criterion for sharpness corresponds to a circle of confusion of ·002 ins.?

$$c = \cdot 002;\ n = 4;\ R = 2$$

$$\text{Total depth} = (u_2 - u_1) = 2cnR(R + 1)$$

$$= 2 \times \cdot 002 \times 4 \times 2(2 + 1)$$

$$= \cdot 032 \times 3$$

$$= \cdot 096 \text{ ins.}$$

Books: *Introduction to Applied Optics* (2 vols), by L. C. Martin (London); *Photographic Optics*, by A. Cox (London).

OPTICAL CEMENT. Adhesive used to bind elements. The oldest is Canada Balsam, but now synthetic resins are used. An optical cement must have a suitable refractive index to match that of the glasses being cemented, as well as resistance to variations in humidity, temperature, etc.

See also: *Adhesive.*

OPTICAL CONTACT. Contact between two surfaces signifying that there is no space left between them; when two transparent surfaces —e.g., the components of a lens—are in optical contact the join thereafter behaves as though it were a single surface separating the two components. Absolutely matching surfaces in contact may adhere without adhesive.

OPTICAL DESIGN

As generally understood, optical design comprises two related activities, which may be described as optical engineering, and as optical design proper.

Optical Engineering. This field covers those studies which indicate the general form of the system to be developed. In earlier times this was a comparatively straightforward matter, but with the application of optical systems to a wider range of use it has taken on an entirely new complexion.

The general framework of an optical system must be developed so that it will fulfill conditions such as the following:

(*a*) An image of adequate size should be formed on a desired receptor. This may be the retina of the human eye, a photographic plate, a sensitive surface of a xerographic type, a photo-electric surface in a television tube, an infra-red or an ultra-violet detector used in a scanning mode;

(*b*) An image of adequate brightness must be formed, so that any of the devices listed above will provide a signal of suitable strength;

(*c*) The system must fit into a stipulated space, which may often require that it be folded with prisms and mirrors;

(*d*) The system must be capable of being fabricated from materials which will transmit desired spectral regions and which will stand up to severe environmental conditions. Such materials must also be available in sizes which will satisfy the needs of the system.

The application of photographic and allied techniques to the wide range of problems in the modern world means that a photographic lens is only one special kind of optical system; many other types may be needed to obtain desired results.

Designing the System. Once the general form of an optical system is determined, whether it be a simple photographic lens or a really complex system, the next stage is to design it in such a way that it provides an image of acceptable quality. This is optical design proper.

In order to provide perfect image quality a lens or optical system must bend the light rays from an object point so that they converge in an image point, and this point must lie in the proper place. The failure of a lens to provide this perfect performance is due to the presence of aberrations. The following basic types of aberration are recognized:

(*a*) Spherical aberration, which gives a circular patch of light instead of a point image.

(*b*) Coma, which produces a light patch flaring away like the tail of a comet.

(*c*) Astigmatism, which produces a light patch that can be changed to a short vertical or horizontal line by shifting the focal plane.

(*d*) Chromatic aberrations, which produce colour fringing of either a symmetrical or of an unsymmetrical form.

(*e*) Distortion, which causes a square object to be reproduced either as an approximate square with concave (pin cushion) or convex (barrel) shaped sides.

It is the responsibility of the optical designer to correct these aberrations so as to obtain the best possible quality. A considerable body of

mathematical theory has been built up which analyses the character of these aberrations.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The simplest group are known as the Seidel or third order aberrations, and fairly simple mathematical expressions are available to deal with these. Beyond this point it is necessary to trace rays of light through the lens. At each surface it is necessary to calculate first where a ray encounters it, and after that to calculate in detail how it is refracted at that surface.

Rays and Ray Tracing. There are two distinct classes of rays, meridional rays and skew rays. A meridional ray is one which lies in a plane containing the axis of symmetry of the lens. A ray which does not lie entirely in this plane is a skew ray.

The tracing of meridional rays is a much simpler and less time consuming activity than tracing skew rays. As a rough estimate it can be stated that, in order to trace a meridional ray with a simple desk calculator, the time needed is about two minutes for each surface that the ray encounters. To trace a skew ray under the same conditions requires about 15 minutes, and the chances of arithmetical errors are much greater.

In the days when all ray tracing was done with desk calculators the labour of designing was very heavy. It was the rare exception to trace skew rays, and the total number of rays which were traced in the intermediate design stages would not normally exceed about fifteen. At the present time all serious optical design is carried out on electronic computers. On even a slow machine the time to trace a skew ray across a surface is about 1½ seconds (compare this with 15 minutes!) while on a reasonably fast machine the time is less than ¼ second. About ninety-six rays will be traced at the intermediate design stages.

At the final evaluation stages it is not at all unusual to trace about a thousand rays or more. The intersection points of these rays in the focal plane of the system are plotted (using automatic machines) to produce a spot diagram, comprising points or spots whenever a ray meets the focal plane. From these spot diagrams it is possible to obtain a much clearer idea of what the lens performance will be.

The advent of electronic computers in the past few years has made a revolution in lens design. The laborious process of ray-tracing once set the pace for design development. This is no longer the case and the emphasis has been shifted towards the development of higher and higher levels of performance. In particular the use of computers has made it possible to design zoom lenses of outstanding performance, an achievement that would have been much more difficult if ray-tracing still had to be carried on by hand.

Automatic Design. This is logically the next step. An electronic computer is capable of making decisions when it is given a suitable criterion by which to operate. If then a computer carries out a ray-tracing programme it can examine the results it obtains, it can make suitable changes in the radii, separations and thicknesses of lenses which should improve the overall performance, and then go into a new ray-tracing programme. This cycle can be repeated until it seems that no further improvement is possible.

Such a process of automatic lens design is no longer a visionary goal. Several programmes directed towards this end are now in use throughout the world. They still need improvement in order to produce results which will satisfy the human designers employing them, but it appears that this is a matter of detailed refinement rather than of establishing new principles.

A.C.

SPOT DIAGRAMS. Rays can be traced through a lens by a computer which directly prints out the distribution of the different rays corresponding to an object point in the image plane. This then indicates the shape and image spot takes in the presence of various optical aberrations. 1. Shape of the light patch in the presence of astigmatism. 2. Coma. 3. Spherical aberration. Each point represents the intersection of a light ray with the image plane. 4, 5, and 6. Light patches obtained with a mixture of aberrations. These light patches were obtained with a fairly simple 8 in. lens and are magnified 300 times (2, 3, and 6) or 1,000 times (1, 4, and 5).

OPTICAL FLAT. Filter and other optical element made to a specially high degree of accuracy with both surfaces absolutely flat and parallel. Filters used for particularly exact photography must be optical flats but they are unnecessarily accurate—and expensive—for the requirements of normal photography.

In practice, minute errors still occur in the accuracy of optical flats. Departures from flatness are expressed in terms of light wavelengths, and from parallelism in terms of minutes or seconds of arc.

OPTICAL GLASS

The modern photographic lens uses a variety of glasses for its construction and in providing glasses of the appropriate properties, many stringent requirements have to be met.

Ideally a lens should reproduce a point as a point and a straight line as a straight line in the plane of the photographic plate even though the various parts of the subject are at differing distances from the lens. In practice a simple lens departs from the ideal, first because defects arise from the fact that the lens surfaces are spherical in form and secondly because glass itself disperses white light into its components and thus produces a spectrum instead of a point image at its focus.

In practice the various defects or aberrations of the simple lens are reduced to a minimum by a proper choice of glasses with the appropriate curvatures used in combination with one another, but at its best the composite lens is a compromise between one aberration and another. The larger the aperture and the greater the curvature of the lens surfaces the more difficult it becomes to reduce the aberrations, and the evolution of the modern photographic lens has depended largely on the development of optical glass.

Use of Different Glasses. The production of a spectrum at the lens focus (chromatic aberration) was considered by Newton to be the chief obstacle to his design of refracting telescope. Between the years 1726 and 1760, Chester Moor Hall and John Dollond showed that chromatic aberration could be reduced by combining a positive lens of a crown glass (low refractive index and low dispersion) with a negative lens of a flint glass (high refractive index and high dispersion). With the glasses existing at that time it was possible to achromatize only for two wavelengths and there remained a residual chromatic aberration called secondary spectrum.

The history of the development of optical glass is largely concerned with attempts to produce glasses to give a reduced secondary spectrum. The important effects of boron and barium in the composition of the glass were discovered by Sir George Stokes and the Rev. Vernon Harcourt in England, and the effects of many other elements were explored systematically by Abbe and Schott in Germany. Many of the glasses so developed had to be abandoned but a few glasses were sufficiently stable to be produced commercially and by their use the apochromatic lens which achromatized at three wavelengths became possible. Such glasses had relatively low refractive indices so that their use was restricted.

Modern glass type for optical purposes include a wide variety of different crown and flint glasses. The term crown glass still remains as a generic description for low dispersion glasses (V-value above 50 to 55) while flint generally applies to glasses of a V value below 50. In addition glasses with a refractive index below about 1.6 are frequently referred to as "light" and glasses with a higher refractive index as "dense". Glasses above 1.7 are extra dense types. Frequently the main addition to the glass melt is also indicated, so that there are barium crown and barium flint glasses, zinc and borosilicate crowns, lanthanum crowns and flints, etc.

While early optical glasses mainly comprised a range from low to medium-refracting low-dispersion crowns up to highly refracting and high-dispersion flints, the development of modern glass types brought highly refracting glasses of medium and even low dispersion into the range. These include rare-earth glasses like lanthanum flints and crowns and thoria glasses.

The value of high-refractive crown glasses is that they can be combined with low refractive glasses of the same dispersion value (the light crown types) to provide colour correction over a wide range of wavelengths.

Homogeneity. The glasses available to Moor Hall and Dollond were found to be inhomogeneous and the sharp variations in composition, which appeared as striations, rendered the glasses unsuitable for optical purposes. The process of eliminating the striations by stirring the glass in its molten state was investigated by a Swiss, P. L. Guinard, in the years 1768 onwards, and by Faraday at the Royal Institution, and this process forms the basis for modern optical glass making technique. Faraday at the Royal Institution conducted experiments on homogenizing, the glass being melted in platinum trays. The methods of Guinand were first tried out on a production scale in England in 1848.

The methods followed in the manufacture of optical glass have developed rapidly over the last 25 years but in all processes stirring is a necessary phase to eliminate inhomogeneities. Prior to World War II, stirring techniques were very similar in principle to those developed by Guinard. At this time, each glass was melted individually in a crucible or pot and usually the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

OPTICAL GLASS TYPES. Glasses are specified by their refractive index (n) and dispersion (ν). The diagram shows available glass types of different dispersions and refractive indices. By tradition, glasses with an Abbe number above about 50 to 55 are termed crown glasses (to the left of the heavy broken line); glasses of higher dispersion (lower ν value) are flint glasses. The divisions indicate the most commonly used terms for the glass types, partly specifying also their chemical composition. Crown glasses: FSC, fluorosilicate crown; BSC, borosilicate crown; C, crown; BAC, barium crown; DBC, dense barium crown; SBC special barium crown; LAC, lanthanum crown; DLC, dense lanthanum crown. Flint glasses: ELF, extra light flint; LF, light flint; MF, medium flint; DF, dense flint; EDF, extra dense flint; BLF, barium light flint; BAF, barium flint; DBF, dense barium flint; SBF, special barium flint; LAF lanthanum flint; DLF, dense lanthanum flint. The solid circles represent glasses available at around the turn of the century; open circles indicate glasses developed up to about 1950 and open triangles are glass types produced since then. These include virtually all the lanthanum glasses as well as rare earth types.

whole pot was allowed to cool and crack up. The cooling was carried out under controlled conditions so that large lumps of glass were obtained and these rough lumps were re-softened and moulded into slabs in order to allow a critical quality examination to be carried out. Glass defective either because of bubble inclusions or striations was cut away and the resultant glass sold either as slabs or as re-moulded lens blanks.

At a later date, the pots were preserved and the contents cast into a large block. Such a block was kept whole by careful cooling and when cold it was polished to allow optically good parts to be located. These were cut away by diamond charged saws and finally processed to the shape required. By either of these processes, precise control of optical properties, homogeneity and bubble quality was difficult, with problems arising from failure to re-produce melting and stirring conditions precisely. Whilst these problems have not been entirely resolved by the modern continuous process, the new technique is such as to allow a greater degree of control to be imposed on all phases of the process with the consequent advantages of reproducibility of optical properties and improved glass quality. In this process, raw materials are fed continuously into a melting unit of special design in which the glass is successively melted and fined off to remove solid and baseous inclusions. Finally it is stirred and formed continuously into bars, blocks or pressings suitable for processing to the optical designers final requirement.

Reference has already been made to the importance of chemical homogeneity and the necessity of stirring to remove sharp variations in composition. The homogeneity of glass is also dependent on a past thermal history and it is important that this should be uniform throughout the glass in order to achieve uniformity of glass structure and hence uniformity of optical

properties. To achieve these necessary requirements all optical glass is annealed to special cooling schedules.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

In the most modern method of manufacture, raw materials are fed continuously into a melting unit of special design. In this unit, the glass is successively melted, fined off to remove solid and gaseous inclusions, stirred, and finally continuously formed into bars, blocks and pressings suitable for processing to the optical designers' final requirements.

Requirements of Optical Glass. The precise requirements of optical glass are:

(1) The glass must have accurately defined values of refractive index and dispersion, repeatable from one melt to another for the same type of glass.

(2) The glass must be uniform in respect of both chemical composition and physical state. Uniformity of chemical composition is achieved in the stirring process and physical uniformity, that is, uniformity of refractive index in a glass of a uniform chemical composition, is achieved by precise annealing.

(3) It must transmit as much light as possible and must not absorb selectively light of different wavelengths.

(4) It must be as free as possible from bubbles.

(5) It must be as resistant as possible to the action of water vapour and other gases present in the atmosphere.

(6) It must be as resistant as possible to the action of acidic materials used in grinding and polishing.

PROPERTIES OF TYPICAL OPTICAL GLASSES

Type	*Refractive Index (nd)*	*V**
Fluor crowns, borosilicate crowns and hard crowns	1·465–1·525	70–59
Barium crowns	1·552–1·657	63–51
Barium flints	1·551–1·700	55–41
Flints	1·542–1·927	47–21
Special rare earth glasses	1·642–1·744	58–44

*The *V*-value is a measure of the dispersion; it is a function of refractive index *nd* (helium *d* line) and the difference in refractive index for the hydrogen *C–F* lines. The lower the *V*-value, the higher the dispersion.

On account of the rather unusual chemical composition of many optical glasses it is often not possible to achieve all these requirements in a particular glass, but clearly the optical properties and homogeneity must take first place and the other requirements must follow. It is not always possible, for example, to achieve a glass of the highest durability because its chemical composition has to be such as to give abnormal optical characteristics. In such a case, it may be necessary to accommodate the component at an internal position in the lens so that its surfaces are protected.

Manufacturing Methods. The pot process is being increasingly superseded by continuous melting processes. These enable the optical properties of glass to be maintained to very close limits over long periods of time and also make it possible to manufacture large slabs of optical quality glass which are needed for such purposes as protective viewing windows in atomic energy facilities and similar situations.

As with the classical pot process, stirring is an essential feature of this new technique, as compositional variations, arising for example from selective volatilization of the constituents and from corrosion of refractory material, must be removed from optical glass. This continuous process enables glass of a high degree of homogeneity and freedom from bubbles to be produced. The main commercial problem remaining is that the quantities produced are large and it therefore becomes necessary to limit the number of types of optical glass that can be manufactured in this way to those that are needed in substantial quantities.

The continuous process is subject to patent protection and also considerable secrecy as to the exact details of manufacture. In general terms the glass is melted in a rectangular bath, heated largely by electrical conduction, and the melted but bubbly glass is then submitted to a "fining" process for which equipment made in platinum is used. After the glass has travelled through the fining system it is stirred mechanically, again in platinum apparatus, in such a way that every portion of the glass is subjected to the same treatment and the uniformity of the product is thereby assured. With electric heating, the temperature in the various stages of the process can be controlled over long periods of manufacture to within 1 or 2° C. and the effects of volatilization, which were so serious under older pot methods, have virtually been eliminated.

The continuous stream of glass which emerges from the stirring equipment may be converted into individual pressings, appropriate to the lenses that are to be made. This involves the use of automatic pressing machines fed from the glass stream with drops of controlled weight. Alternatively, the glass may be converted into continuous strips from which a variety of lens or prism shapes can be produced, or can be flowed into large moulds in order to produce large slabs. Slabs produced by this method in the normal course of manufacture can be up to 6 feet square and 1 foot thick and can weigh a ton or more—a far cry from the haphazard selection of small pieces of bottle glass which were all that were available to the earliest optical designers.

The use of platinum equipment has eliminated the contamination that used to occur by the solution of the refractory materials used as a container, and also has simplified the removal of bubbles, many of which were produced by the interaction of the constituents used for the glass and the ceramic pot.

At the same time, there are some technical limitations to the continuous method. Glasses with extreme optical properties can give rise to

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

trouble due to volatilization and refractory solution. The colour of a glass is primarily determined by the choice of raw material and by impurities taken into the glass as a result of refractory corrosion. The chemical elements used for the manufacture of the more extreme glasses are more liable to give rise to difficulties over both volatilization and refractory corrosion. Consequently, with these glasses, the technique involving the use of pure platinum crucibles heated in electric furnaces has been maintained. Materials such as lanthana, thoria, cadmium, tungsten, are used in the manufacture of these special glasses in order to produce the wide range of optical characteristics required for specialized design.

The use of platinum crucibles in electric furnaces also continues to some extent for types of optical glass that are needed in relatively small quantities, for instance, in the manufacture of microscope lenses. The cost of manufacture in this way is notably higher than that of the production of optical glass by the larger scale continuous process.

Both methods of manufacture—the continuous process and the platinum pot process—are under continual investigation in the research laboratories and in the works of optical glass manufacturers, with particular effort being directed towards the problem of improving control of both glass quality and optical properties. It is anticipated that this requirement for tighter control will become progressively more important as a result of increasingly tight specifications being imposed on the optical properties by new and more sophisticated lens design. At the same time, new and improved glasses are being developed and it is clear that this work, in due course of time, can lead to some redundancy in existing glass types.

OPTICAL SENSITIZING. Method of extending the spectral sensitivity of an emulsion by the use of dyes. The basis of all ortho and pan emulsions. Either the emulsion or the coated plate may be treated, and the extra sensitivity depends on the dye, e.g., eosine will sensitize an "ordinary" blue-sensitive plate to yellow light, cyanine will sensitize it to red. Other dyes can sensitize emulsions to invisible radiations (infra-red rays). The patent literature lists many sensitizing dyes.

See also: *Negative materials; Sensitizer; Spectral sensitivity.*

OPTICAL WEDGE. Device used in sensitometry to measure the effect of a range of exposures on a laboratory sample of sensitized material. It generally consists of a strip of material—glass, celluloid or plastic—covered with a pigment or developed silver emulsion layer which is clear at one end and gradually becomes opaque towards the other. The transition from transparent to opaque may take place smoothly (continuous wedge), or in regular steps, in which case it is called a step wedge.

See also: *Sensitometry; Wedge.*

OPTICS. Branch of science concerned with the behaviour of light. There are three main divisions of the subject: physical, physiological and geometrical. The first is concerned with the composition and character of light. The second is concerned with light in its relation to human vision. The third division deals with the geometry of the paths followed by light rays under particular conditions—e.g., when passing through a lens or after reflection from a polished surface.

See also: *Colour; Illumination; Image; Lens; Light; Mirrors; Optical calculations; Projection principles; Refraction; Reflection; Vision.*

ORDINARY EMULSION. Term used to describe a "colour-blind" or blue-sensitive emulsion to distinguish it from an orthochromatic or panchromatic emulsion.

See also: *Negative materials; Sensitized materials history.*

ORTHOCHROMATIC. Materials which are sensitized to all the visible spectrum with the exception of the deep orange and red rays. Orthochromatic films used to be popularly known as chrome films, but this suffix is now also applied to panchromatic and to colour films.

See also: *Infrachromatic; Negative materials; Ordinary emulsion; Orthopanchromatic; Panchromatic; Spectral sensitivity.*

ORTHOPANCHROMATIC. (Correct pan). Term used to describe materials sensitized to all colours of the visible spectrum but with an evenly balanced red sensitivity. In this they differ from the excessive red sensitivity of some high-speed panchromatic emulsions which are produced to give speed as a first consideration.

ORTHO-PHENYLENE DIAMINE. 1 : 2-diaminobenzene; ortho-aminoaniline. Fine grain developing agent.

Formula and molecular weight: $C_6H_4(NH_2)_2$; 108.

Characteristics: White crystalline powder.

Solubility: Fairly soluble in water.

ORTOL. Developing agent. Now largely obsolete.

Formula and molecular weight: $2(CH_3NHC_6H_4OH)_2H_2SO_4.C_6H_4(OH)_2$; 798.

Characteristics: White powder. In developers acts somewhat like metol-hydroquinone.

Solubility: Fairly soluble in water.

OSCILLOGRAPH RECORDING

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Technique of recording in graphic form, physical changes against time. Photo-oscillography is the technique of oscillograph recording using light beams or electron beams to expose traces on photographic materials.

History. The first known recording instrument appeared about 300 years ago in Oxford, England, and was used to record temperature as it varied with time. Early recording techniques included the use of a needle to scratch through a smoked surface, previously applied to glass or paper. During its evolution numerous marking methods and materials were tried as increased mechanization of the nineteenth and twentieth centuries created the need for accurate recording media. The development of recorders continued for many years to be centred around mechanical, ink, pressure, heat, and electric marking methods.

In 1867, a photothermograph and a photobarograph were developed and used by the Royal Meteorological Society. These instruments, the first to record photographically, may be seen at the Science Museum, London. In 1897, Sir J. J. Thomson at the Cavendish Laboratory in Cambridge, using a cathode-ray tube for his experiments, measured the ratio of the charge of the electron to its mass. In the same year, Professor F. Braun applied a cathode-ray tube to industrial testing, intiating what is now a universal instrumentation technique.

In the following years, two photographic-marking methods evolved: light-beam recording and electron-beam recording. The acceptance of the photographic-marking methods occurred because of inherent limitations of mechanical, ink, pressure, heat, and electric marking equipment. The frequency response of typical mechanical-stylus recorders was in the 0–100 cycles per second range. In addition, restrictions of size and stylus swing limited the number of information channels and the amplitude that could be recorded on paper of a given width. The advent of photo-oscillography overcame the low-frequency-response limitation; present-day light-beam recorders are capable of frequencies to above 10^4, and electron-beam recorders to above 10^8. Photo-oscillography also made it possible to overlap traces so that as many as sixty channels might be recorded on 12-ins. wide sensitized paper.

Sensing Devices. Physical qualities such as temperature, force, stress, light level, fluid flow, acceleration, displacement, and vibration can be measured by first converting the energy into an electrical signal. In that intermediate form, the energy can be transmitted, processed and converted into measurable data. The sensing device is called a transducer and examples are thermocouples, strain gauges, differential transformers and accelerometers.

Transducers may be active or passive. The active transducer is a calibrated device for converting a small sample of some form of mechanical energy into analogous electrical energy. Examples are piezo-electric and magnetic transducers.

Passive transducers act as valves to control the flow of electrical energy from an outside source. Strain gauges and resistance thermometers are examples of passive transducers.

Transducer output-signal variations, when linked to the oscillograph recorder, cause corresponding variations in sweep of the recording beam. The beam exposes the photo-sensitive material moving continuously past the recording point at a constant rate, leaving a path that is the final trace on the record.

Light-beam Oscillography. Light-beam oscillographs are usually of the mirror-galvanometer type. Light from a source within the oscillograph is reflected from a tiny mirror mounted on the rotating coil of the galvanometer. The coil with its mirror twists in proportion to the electrical current, and the light reflected from the mirror falls on the moving photo-sensitive material. After calibration, the mirror position (and hence the trace) is a measure of the exact amount of current.

Although the mirror-galvanometer is perhaps the most critical component in the light-beam oscillograph, recording cannot occur unless other components are provided. Besides the light-sensitive material and a transport to drive it through the recorder, the light source, the trace optical system, and time reference and other optical systems must be installed in a light-tight enclosure provided with suitable controls. The resulting unique "camera" is the photographic light-beam oscillograph.

These instruments are of two kinds: develop-out and print-out recorders. Develop-out oscillographs use a tungsten lamp to record on

GALVANOMETER OSCILLOSCOPE. A, suspension. B, mirror. C, coil. D, magnet poles. Current pulses going through the coil cause the latter to turn in the magnetic field; a light beam directed on the mirror moves with the latter and can thus trace a record of the movement on a sensitised paper or film.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

GALVANOMETER OSCILLOGRAPH RECORDING SYSTEM. A, light source. B, light beam for recording reference grid on the paper or film. C, main recording mirror. D, grid recording mirror. E, main recording lens. F, surface of recording paper. G, collector lens. H, main recording beam. J, galvanometer mirror.

film or paper which must then be chemically processed to produce a visible image. Develop-out sensitized materials must be handled in a darkroom under recommended safelight conditions; this applies to loading and unloading the oscillograph magazine, as well as to processing the material.

Develop-out records are generally in long roll form which precludes processing by hand methods. Rewind batch-type processors, normally used to develop aerial films, were once widely used for processing oscillograms. Since the mid-1950s, compact, continuous stabilization processors have been used. Table-top stabilization processors develop, stabilize and dry records at a nominal 6 feet per minute. Floor models operate at speeds up to 200 feet per minute. The wash cycle normal to standard photographic processing is omitted, thus speeding up access time. Although the record does not have archival permanence, it will last several years under normal handling and storage conditions. This period is sufficiently long to permit the data to be read. Reproduction of the original record on microfilm produces an archival duplicate that also has the advantage of saving a large amount of filing space.

Oscillograms having multiple trace colours provide the advantage that individual overlapping traces can be easily identified by following the respective trace colour. Colour records are produced by mounting various colour filters on the galvanometers which then reflect coloured light on to special colour-recording paper. Following exposure, the paper is processed in a stabilization processor, after its tanks have been filled with colour-processing chemicals.

Print-out recorders use a paper that produces a visible trace without chemical processing. Print-out paper is relatively slow, as compared with develop-out paper; therefore, a higher intensity light source must be used in the recorder. Usually, the lamp is a mercury or xenon arc lamp, but improvements in the sensitivity of print-out materials have enabled high-intensity incandescent lamps to be used in some lower writing-speed applications.

After the traces are exposed, the paper must be given a second exposure, called latensification, to make the latent image visible. The second exposure can be made to room light, but most modern oscillographs are equipped with built-in latensification lamps. Subsequent exposure of the record to ultra-violet or excessive, prolonged or repeated exposure to room light will degrade and eventually obliterate the trace image. The record will also be rendered useless if it is duplicated with reproduction equipment having high-intensity light sources. However, the image of some print-out papers can be given a chemical-stabilization treatment, which renders it permanent and capable of reproduction in any equipment.

Emulsions, whether develop-out or print-out, are coated on both light-weight and heavy-weight paper base. The lightweight paper allows duplicates to be made on standard diazo and similar office reproduction machines.

Electron-beam Oscillography. The advantage of electron-beam recording over other recording methods is that the electron displacement is virtually inertialess. Therefore, very high-frequency recording is possible, and performance is believed to be the highest of any existing recording method. Recording can take place either directly by exposure from electrons, or indirectly by photographing the luminiscent trace on the face of a cathode-ray tube.

Direct Exposure. In practicing the direct-exposure method, special electron-sensitive recording film is used; its emulsion is particularly sensitive to electron energy and relatively less sensitive to photon energy. The sensitized material is placed inside the special recording tube, the tube is evacuated, the electron-beam

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

OSCILLOSCOPE CAMERA. This consists of a camera back and lens, usually with shutter, set for a close-up distance and mounted on the front of the oscilloscope screen to record the trace on the latter. Top: *General view with camera unit swung away on the light excluding tube.* Bottom: *Side view.* A, *eye-piece for visual observation of the oscilloscope screen.* B, *camera back.* C, *lens and shutter unit.* D, *light-excluding hood, also holds the camera lens at the correct close-up distance.* E, *oscilloscope screen.*

exposure is made, the tube is returned to normal pressure and opened, and the film is removed and processed.

Indirect Exposure Exposure by light emitted by the phosphorescent screen of a cathode-ray tube, when its phosphor coating is activated by electrons, is the more common technique. The widespread use of oscilloscopes and improvements resulting in high-speed, high-resolution sensitized materials, popularized phosphorescent-screen cathode-ray oscilloscope photography. Today, the oscilloscope is used in nearly every laboratory, and single-shot recording cameras are available to fit nearly every make of instrument. It is easy to make and to assess photo-oscillograms made on such equipment, particularly when instant-processing materials are used as the recording medium. Because of its universal use, the oscilloscope and the recording of single shot cathode-ray tube images has been well documented in electronic and photographic literature.

The standard technique for photographing the cathode-ray trace uses an oscilloscope camera, but a still camera can also be employed. In either case the camera is focused on the cathode-ray tube screen and is usually mounted at the end of a light-excluding hood. The camera can record either continuous events in which the electron-beam follows the same repetitive path for a period exceeding the exposure time; or separate events in which the beam makes one trace only per single transient.

In the first case, the camera exposure can be as long as necessary to obtain a satisfactory record. In the second case the shutter is opened just before the trace occurs and is kept open for its duration. This may necessitate a fairly wide lens aperture and fast film, particularly at high writing speeds of the spot. Special instant processing materials are available for oscilloscope photography that have speeds as high as 10,000 A.S.A. equivalent, which greatly simplifies the exposure problems.

Special cameras are available for recording transient events that occur at random, and/or which may be prolonged and vary continuously. In this case the film moves continuously at a constant speed thus providing the time axis (just as paper is transported in the light-beam oscillograph). Therefore, the time base of the oscilloscope is switched off so that the spot moves only in the amplitude scan.

Transient events can also be photographed in a similar manner on a drum camera. Cameras of this type are capable of very high film-travel speeds. H.W.H.

OSTWALD, WILHELM, 1853–1932. German professor of physical chemistry at Leipzig University. Introduced a new theory of colour and published his Colour Atlas which embodied a system of colour tabulation commencing with pure hues to which were added varying proportions of black and white. Invented the Katatype process for colour prints (1902). Proposed theories on the chemical development of the latent image and on the ripening and growth of the grains in an emulsion. He received the Nobel Prize for Chemistry in 1909. Autobiography: 1926/27.

OVER-DEVELOPMENT. Fault indicating that the developing solution was allowed to act too long on the sensitized material to produce an acceptable result.

Negatives. An over-developed negative looks dense and contrasty. The shadow detail is well graded, but the highlights are clogged and extremely dense. Such a negative can easily be distinguished from one that has been over-exposed but correctly developed. The over-exposed negative is dense but flat, and even in the darkest areas the shadows are veiled.

A normal print from an over-developed

negative is harsh and contrasty; the shadows print out in solid black and the highlights are chalky and featureless.

CC-0. Agamnigam Digital Preservation Foundation Chennai

Assuming that the developer is correctly mixed and fresh, over-development may be caused by errors in working out the development time for the particular combination of sensitized material and developer. Or it may be due to faulty timing or to over-agitation. Other possible causes are that the developer concentration was too high, or the development time did not allow for a temperature change.

When developing by inspection, over-development may be due to the photographer's inability to judge the appearance of a fully developed negative.

An over-developed negative may be bleached and redeveloped, as in intensifying, or it may be reduced by a suitable reducing bath. The exact treatment adopted will depend on the contrast of the negative, a different method being adopted according to whether the contrast is to be unchanged or reduced.

If the amount of over-development is slight, it may be sufficient to print on a soft grade of paper. In this case the increased density of the negative is partially offset by the higher speed of the soft paper.

Over-development can be avoided by mixing and using the developer according to the maker's instructions and by using a reliable developing chart which takes into account the differences in all the current kinds of sensitized material and developer, and makes allowances for temperature, agitation, age, and exhaustion of the solution.

When developing by time and temperature it is always advisable to work to a darkroom timer that rings a bell at the end of the required development period.

When developing by inspection it is generally safe to stop development when the shadow detail can be seen showing through the back of the emulsion.

Over-development should always be avoided with miniature negatives as it produces an increase in the grain size.

Prints. When a print has been correctly exposed, development for considerably longer than the recommended period has no serious effects; it may, in fact, give a richer print. If continued for too long the print will become fogged and stained and the image colour will alter.

Over-development with normal exposure can be distinguished from over-exposure with normal development without much trouble. The over-exposed print very rapidly builds up density in the developer and is more or less black and obscured before there is time to do anything about it.

Since prints are developed by inspection, the only reason for continuing beyond the correct time is inability to recognize a fully developed print. The tendency is in any case to take the print out of the developer too soon; leaving it in longer does no harm, up to a point, provided the exposure was correct in the first place.

A possible cause of over-development of bromide paper is that the developer was mixed to contact paper strength.

There is no difficulty in avoiding over-development once the characteristic appearance of a fully developed print has been learned by experience. In any case it is not possible to over-develop a correctly exposed print if the maker's instructions on mixing and using the developer are followed.

Contact prints are normally fully developed in about twenty to thirty seconds, and bromide prints in two to three minutes. F.P.

See also: *Developing negatives; Developing prints; Faults; Over-exposure.*

Book: *Developing*, by C. I. Jacobson (London).

OVER-EXPOSURE. Fault indicating that the image formed on the sensitized material was either too bright or allowed to act too long during exposure.

Negatives. An over-exposed negative looks dense and blocked up. The shadow detail is all there, but it is usually veiled over with a deposit of silver while the highlight areas look completely opaque.

In extreme cases the whole negative looks black with only a hint of an image in the deepest shadows.

An over-exposed negative can be distinguished easily from one that has been correctly exposed but over-developed. The over-exposed negative tends to be flat and lacking in contrast, because all the tones, given long enough exposure, would record as dense deposits while the brightest highlights could add no further density. The over-developed negative tends to be excessively contrasty. This is because the highlights go on developing at a disproportionately greater rate than the shadows.

A print from an over-exposed negative, on a normal grade of paper, tends to be flat and muddy. It may, however, yield an acceptable print on a harder grade of paper, but in either case the excessive density means that it will take a long time to print.

Over-exposure may be caused by inaccurate estimation or measurement of the prevailing light, by incorrect setting of the shutter speed and lens aperture, or by a faulty exposure meter or camera shutter. In flash photography it may be the result of an error in calculating the stop and subject distance from the flash factor. It may even be caused by using a developer that increases the effective film speed.

The commonest cause of over-exposure is undoubtedly human error. The photographer either does not use the meter correctly, or interprets its reading literally instead of making allowances for such factors as subject contrast, filter, film speed, light direction and colour temperature, and type of developer to be used. Owners of single lens reflex cameras frequently

focus at full aperture and then forget to stop down before exposure.

Over-exposure in extremely cold weather is often the result of shutter lag caused by coagulated oil or, in focal plane shutters, by hardening of the roller blind fabric.

Generally speaking, over-exposure is much less serious than under-exposure because all the detail is there, although over-exposure tends to increase the grain—an important consideration in miniature work.

An over-exposed negative can usually be made to yield a satisfactory print on a suitably hard grade of paper. The principal drawback is the long printing time, but there are two ways of avoiding this. One method is to replace the normal printing or enlarger lamp with a Photoflood, in which case the enlarger should always be switched off immediately after the exposure, because of the great heat generated; the other is simply to reduce the negative with Farmer's reducer. As this reducer tends to increase contrast, it partially corrects the flatness of the negative tones at the same time.

Over-exposure can be prevented by using a reliable exposure meter and making due allowances for all the relevant subject, lighting and processing conditions. If, in spite of this, negatives are regularly over-exposed, either the meter or the camera shutter may need checking.

In cold weather the camera should be kept in a warm place and not left in an unheated room where the low temperature may slow down the shutter and give over-exposed negatives.

Prints. An over-exposed print has a heavy, sombre appearance; the highlights are veiled over and the shadows are completely blocked-up areas of deep black tone.

It is not possible to mistake a blackened, over-exposed print for one that has been correctly exposed but over-developed. Even a print that has been developed for two or three times the normal length of time will look little darker than one that has been given the correct development if the exposure was correct; after a very long time the print will become covered with general fog, and there may be stains in places, but up to that point over-development has no other effect.

Some workers over-expose prints habitually, consciously cultivating a gloomy, low-key style of expression.

The cause of accidental over-exposure is usually failure to switch off the light in time, either through faulty timing or carelessness. It may occur in enlarging when the lens is opened up for focusing the image accurately and not subsequently stopped down to the correct aperture for exposure.

Over-exposure may also be the result of changing from one batch of paper to another of the same specification but of higher speed due to manufacturing differences.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Over-exposure can be avoided by making careful tests before exposure on strips of the actual printing paper. Further tests should be made after any major change in magnification or if the lens is stopped down after making the test exposure. (In many enlargers the optical conditions are such that when the lens is stopped down, the light passing through is not reduced in proportion to the aperture numbers.) F.P.

See also: *Exposure; Faults; Over-development.*
Book: *Exposure*, by W. F. Berg (London).

OVERHEAD PROJECTOR. Still projector for projecting large-size transparencies, including diagrams and plans drawn on a transparent or translucent support. The transparency is placed on a horizontal illuminated light box and a lens projects the image forward via a 45° mirror mounted some distance above the light box. Used for certain educational and industrial purposes.

See also: *Projector (still).*

OVER-RUN LAMP. Lamp which is deliberately run on a higher voltage—and at a higher temperature—than normal—e.g., Photofloods. This greatly increases the light output and efficiency, raises the colour temperature, but appreciably shortens their life (often to a matter of a few hours).

See also: *Filament lamp.*

OXALIC ACID. Used in certain toners, also used as a preservative of pyro solution.

Formula and molecular weight: $(CO_2H)_2 \cdot 2H_2O$; 126.

Characteristics: White crystals. It is poisonous.

Solubility: Fairly soluble in water at room temperature.

OX GALL. Commercially prepared liquid used by photographic retouchers and artists for treating a glossy surface—e.g., of a print or slide—to make it accept pigments applied with a brush. Also used in glazing prints.

OXIDATION. Chemical reaction increasing the proportion of oxygen or similar electronegative components of a chemical compound (or decreasing the proportion of hydrogen or similar electropositive components). Thus conversion of a silver image into silver halide by a ferricyanide and bromide bleacher consists of oxidation of the silver to silver bromide (here bromine is the electronegative component):

$$K_3Fe(CN)_6 + KBr + Ag = K_4Fe(CN)_6 + AgBr$$

Every oxidation is necessarily accompanied by a reduction, i.e., the increase of the proportion of the electropositive component of a compound. In the above example potassium

ferricyanide $K_3Fe(CN)_6$ is at the same time reduced to ferrocyanide $K_4Fe(CN)_6$, potassium (K) being the electropositive component.

Similarly, during development silver halide is reduced to silver while the developing agent is oxidized.

OZALID PROCESS. One of the diazotype printing processes used principally for making positive prints from tracings of draughtsman's drawings.

Special paper, sensitized with a diazo compound and a colour coupler is exposed behind an ordinary line tracing and developed either with ammonia vapour or by damping it slightly with a dilute alkali.

The image normally develops as reddish-brown lines on a faintly purple tinted ground.

As the paper is not processed wet, it does not change dimensions and the print is reasonably true to size.

See also: *Document photography; Printing processes (Obsolete).*

OZOBROME PROCESS. Fore-runner of the carbro process. In common with carbro the process gives pigment prints direct from bromide contact prints or enlargements without the action of light. It was invented by Thomas Manly in 1905.

See also: *Printing processes (Obsolete).*

OZOTYPE PROCESS. Method of pigment printing invented by Thomas Manly, 1899, later replaced by the ozobrome process. One of the many processes which finally led to present-day carbro printing.

P

PACKING AND SENDING PHOTOGRAPHS. Of the thousands of prints and transparencies that are sent through the post, a high proportion arrive in bad condition—bent, creased, dog-eared, and in some cases even torn or broken. Often valuable photographs are worthless when they are received at their destination. Too often the Post Office gets the blame when in fact the trouble lies entirely with the sender.

A finished picture represents such an expenditure of time and trouble that it is worth while taking the little extra trouble in packing it to ensure that it reaches its destination in first-class condition.

Unmounted Prints. The method of packing depends largely on the number being sent and their size. Small prints will usually go into an envelope with stiffeners to keep them flat. The envelope must be of the strongest type; some of the cheaper varieties tear very easily. Stiffeners can conveniently be cut from strong cardboard and should be slightly larger than the prints themselves. One is placed on each side of the prints and the sandwich is held together with rubber bands.

Larger prints usually have to be parcelled and the packing materials should be selected carefully. The prints themselves should be sandwiched between strong cardboard stiffeners, while the corners and edges should be protected with corrugated cardboard held in place with string or adhesive tape. The parcel is then wrapped up in strong brown paper and fastened securely with string. Cellulose tape is also useful for holding down the edges of the parcel and prevents the paper from being torn off in transit.

An alternative method is to roll the print up and pack it in a stiff cardboard tube. This protects the prints against almost all risks of injury short of deliberate damage.

Mounted Prints. The mount itself is stiff, but that does not mean that packing can be skimped. Where there are several prints they should be packed in pairs face to face, with the surfaces protected from abrasion by tissue or other soft paper. The stiffeners should be of heavy board just larger than the mounts and corrugated cardboard should be used around the edges. (It is often advisable to use a sheet of thin plywood in place of one of the stiffeners if the prints are very large, very valuable, or have to be sent overseas.) The parcel is finally wrapped in stout brown paper and well tied and sealed.

Exhibition prints are often sent in specially constructed flat cases made of hardboard or plywood. This inevitably increases the weight of the parcel, but affords much greater protection for the contents and provides a convenient storage place for prints at other times.

The address should always be written clearly in block capitals and in addition, the name and address of the sender should be plainly stated. It is also important that the name and address of the sender is written either on the enclosed prints or on a covering letter included with them. This enables the prints to be returned to the sender if the outer wrapping should be torn off or obliterated.

How the prints are sent through the post will depend on the number being sent. A parcel of up to four mounted prints, size 16 × 20 ins., can be sent by letter post. Larger numbers may be sent by parcel post up to a weight limit of 15 lbs. Letter post is usually the quicker of the two. Either way the parcels can be registered.

When prints are sent overseas the sender may have to complete a customs declaration form stating the contents of the parcel and the estimated value. This is then stuck on the outside of the package. Prints conveyed by parcel post abroad cannot be registered but they can be insured, which amounts to the same thing. Details of postage, registration or insurance can be obtained from any Post Office.

In the U.S.A. prints may be mailed either 1st class or 4th class. In the latter case the package must be open for inspection (equivalent to British printed matter postage).

Transparencies. In most cases the value of a transparency—especially in colour—is greater

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

than that of a print. Careful packing is even more important to avoid possible damage or loss. It is usual for transparencies to be either mounted between glass or else slipped into a transparent paper or plastic bag for protection. Even cardboard-mounted 35 mm. transparencies should be protected in such an envelope.

It is almost impossible to pack glass slides in such a way that breakage is impossible, but it is quite easy to take precautions that reduce the risk to a minimum. The secret is in packing the slides tightly. A stout cardboard box should be used, into which the slides fit exactly. Pack any vacant space tightly with folded newspaper or corrugated cardboard. Leaves of paper between the slides can be included, but are not essential. The lid of the box must not be neglected. This too should be padded out so that when the lid is on the slides cannot move in any direction. Plenty of corrugated cardboard should then be bound round the box in both directions before the usual outside packing is completed.

Although a strong cardboard box will give adequate protection in most cases, a wooden, or metal box may be more suitable if slides are being dispatched in quantity. The interior of such a box should first be lined completely with some sort of padding, and the slides packed tightly as before. But batches of more than six in one box will be safer if wads of corrugated cardboard are interspersed at intervals.

Transparencies without glass mounts will also travel best in a strong cardboard box. Care should be taken to see that they remain flat in the box, and plenty of padding with folded newspaper will give added protection.

Quick Delivery. From time to time photographs have to be got away in a rush, and the normal postal service would be too slow. One quick way is to take the parcel or packet to the railway station for despatch by train. British Railways will accept parcels for dispatch by the first available train on either weekdays or Sundays. The parcel is clearly marked "To be called for" at the distant station and the addressee is advised by telephone or telegram to meet the train and collect the parcel.

Photographs may also be sent by express post all the way to their destination, but this is quite a costly business if they have far to go. A cheaper way is to send them by express Railex. In this case the Post Office dispatches the parcel by messenger to the station where it is put on the first available train. It is collected at the station nearest to its destination by another messenger and taken to the address. The weight limit for parcels sent in this way is 1 lb.

A parcel for an overseas address can also be delivered by express post when it reaches the immediate neighbourhood of its destination. This service is available in certain countries only; it is arranged through the Post Office where full particulars can be obtained of the places served and approximate delivery time.

No special express service is available for photographic prints in America, but the Western Union messenger service is often used for this purpose within localities and the various air express services throughout the country will dispatch such materials from coast to coast within hours. G.W.P.

PAINTING AND PHOTOGRAPHY. The influence of painting on photography became apparent from the moment the daguerreotype and calotype processes were published. During past centuries many artists had striven to copy objects as realistically as possible and in 1839 many considered photography as an easy, quick and cheap means towards this end. Paul Delaroche, France's most celebrated artist at the time, summed up this attitude with his classic remark on first seeing a daguerreotype: "From today, painting is dead!"

A high proportion of early photographers were former artists, e.g. D. O. Hill, Henry Collen, Charles Nègre, William Lake Price, O. G. Rejlander, etc. Though admittedly not of front rank, they brought to photography an artistic training in composition and an eye for picturesque effects, and until the mid 1850's they treated subject matter in a straightforward and realistic way. It was only when art critics reviewing photographic exhibitions taunted photography with being a mechanical reproductive process, denying it creative possibilities, that many ambitious photographers tried to prove the opposite by making photographic pictures in subject matter and styles borrowed from painting, and quite outside the scope of photography. Leading spirits in this conscious attempt to raise photography to Fine Art were William Lake Price, O. G. Rejlander and H. P. Robinson. The majority of their fanciful compositions, made by combination printing or photomontage, looked at best like reproductions of paintings, but never like the achievements of an independent art. Yet this desire for recognition as artists led astray many otherwise excellent photographers like Hill and Julia Margaret Cameron, who achieved art when they were least conscious of it.

The photographic Fine Art movement had its centre in the Photographic Society of London, and from here pictorialism gradually spread to wherever photographers met in organizations, and competed in exhibitions. Their exhibition pictures, made as relaxation from the everyday routine work of portrait photography, usually demonstrated extraordinary technical skill, but outside these circles few considered them as Art.

The first open rebellion against artificial picture making was P. H. Emerson's *Naturalistic Photography* (1889), which came at a time when similar movements appeared in literature, drama, and other cultural fields. Soon after this the majority of the new generation of landscape photographers came under the influence

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of Impressionist painting. The understandable wish to dissociate themselves from the mass of new amateurs who were mere snapshooters led to the use of elaborate techniques such as the gum process, which made possible considerable manual interference with the photographic image, thus proving that photography was not mechanical, and frequently resulting in pictures imitating graphic techniques. The aesthetic movement in photography which began in 1892 with the *Linked Ring*, and received great impetus from the American *Photo-Secession* ten years later, was a world phenomenon closely related to the *art nouveau* movement in outlook. This kinship led to the acceptance of photography by many art groups of the period in joint exhibitions, especially in Germany and Austria.

Other *fin-de-siècle* photographers considered it the highest aim of photographic art to make fake paintings in the style of Old Masters.

During and after World War I, under the influence of new movements in art, there sprang up at around the same time numerous similar trends in photography: *abstract photography* (Vortographs by Alvin Langdon Coburn, Schadographs by Christian Schad, Rayographs by Man Ray, and photograms by Moholy-Nagy); *Neue Sachlichkeit* (New Realism) photographs by Albert Renger-Patzsch, Edward Weston and others; *surrealist* photographs by Winfred Casson, Peter Rose Pulham, Angus McBean and others. Of these three movements, only *Neue Sachlichkeit*, which was really a return to the sharp objective photography of the earliest period, with special emphasis on close-ups, has left a lasting mark on the further development of photography.

After World War II the acceptance of abstract art, now no longer experimental but world-wide, also gave photography a new look, largely under the leadership of Otto Steinert's *Subjective Photography*. Over-stressing of the graphic element often led to an attendant loss of photographic halftone and texture—photography's greatest assets. While certain attempts to bring photography into line with contemporary tendencies in art are obvious, the effects are today normally achieved by purely photographic means, and are certainly preferable to the outdated pictorialism still in favour with the older members of many photographic clubs and societies. Photographic documentation and reportage has by its very nature always remained outside the influence of aesthetic trends and painting, and has probably for this very reason developed into one of the most important fields of original expression in photography. H.G.

Book: *Creative Photography: Aesthetic Trends* 1839–1960 by Helmut Gernsheim (1962), London.

PAINTINGS AND DRAWINGS

Photographic reproductions of works of art are used for study by people who do not have access to the original, for magazine and book illustration and for records for art historians and picture restorers. For all these purposes the photograph must be sharp and clear, and as close to the original as possible. In addition to reproductions of whole paintings, some exciting results can be produced with exact size details or even by photographs taken 3–4 times magnified to show the artist's technique, brush strokes and craquelure.

Equipment. The studio equipment necessary is simple, but it must be accurate and strong: a firmly-built square bellows camera to take plates or sheet film, if possible not smaller than whole plate; a first-class modern copying lens with a slot to take gelatin filters; a solid stand with easy raising and lowering movement and an upright easel fixed to a steel frame. The easel must move up and down, and the frame must have a sideways movement. Accessories needed are a lens hood, focusing magnifier, light meter, filters (these can be bought comparatively cheaply and allow the photographer to invest in a large variety for experiment), and the normal darkroom equipment. It is most important to have a dark matt background, preferably black.

Artificial lighting is by far the most satisfactory because its constant nature gives a good basis for judging exposures and makes reflections easier to control. The most effective and reliable permanent lighting set-up is provided by a pair of upright parabolic trough reflectors fitted with 500 watt photo pearl bulbs every 18 inches. The troughs, up to eight feet high, painted white inside and mounted on a stand with rubber wheels or castors, can be easily moved about and give a good even light to cover the biggest pictures.

If, however, the work has to be done in a house or sale room, shallow bowl reflectors on a portable stand taking 500 watt bulbs are quite satisfactory. This type of lighting is suitable fot the amateur.

Sensitized Materials. Sheet films or plates can be used; the latter are dimensionally more stable. But modern polyester film bases are sufficiently stable for most practical purposes.

A soft gradation panchromatic film is best for paintings, and for drawings a slightly more contrasty emulsion. Even with black-and-white drawings it is advisable to use a panchromatic plate. Any discoloration or stains in the paper can then be made visible or subdued by the use of appropriate filters.

When photographing an oil painting, the aim is to produce a soft, clear, fully-exposed negative with plenty of detail in the shadows; with a drawing or water colour a slightly more contrasty, clean-looking negative is required.

Either dish or tank development may be

used, but the negatives must be kept free from grit and blemishes, particularly when they are to be used to show condition, as no retouching must be done at all.

Prints should be made on a smooth surface paper, either unglazed glossy or semi-matt. The expert never uses paper with an obtrusive surface or sepia tone; he knows that he is reproducing a picture, not making one.

Method. The picture to be photographed is set up as upright as possible on the easel, or fixed to some solid foundation if in a sale room or house. The image is then checked to see that it is square on the ground glass and includes the whole of the painting. It is next focused carefully with a focusing magnifier, and the lens is stopped down sufficiently to ensure good definition over the complete area of the plate. Focusing is carried out finally with the filter in position if a filter is to be used. The photographer now stands with his head in front of, and level with, the lens, and examines the picture for reflections, moving the lights about until there are none, and always checking up from the level of the lens.

Next, using a photo-electric meter, a reading is taken on a darkish part of the picture (if it is an oil painting), and the exposure is worked out, allowing for the filter if any. It is generally safe to double the resulting calculation with rich oil paintings as they absorb so much light, and it is important to reproduce every detail. For drawings, a general meter reading should be taken from a distance of about 12 ins. It is easy to cast a shadow over the picture without noticing it, so every care should be taken to prevent this happening.

With a drawing, accuracy of exposure and development is more important than with an oil painting, as the difference between charcoal, pencil and crayon is so slight. Failure to appreciate this fact explains why so many reproductions of fine pencil drawings look as though they have been done with pen and ink. The whole character of the original can easily be lost unless special attention is given to this point at every stage, including the printing.

Whenever possible the picture should be photographed out of its frame so that all the edges show. The edges must never be trimmed off or the result will look more like a picture postcard than a reproduction of a masterpiece.

Filters. Modern films have such a balanced colour sensitivity that filters are not often needed. However, there are times when a filter helps. In photographing a portrait it is quite useful to use the type of filter that is slightly greenish-blue and gives good modelling in the features. This filter can also be used to advantage in photographing pictures during cleaning as it shows up dirty patches of varnish very clearly. Another filter which is useful is the orange-red. This is a help when the picture is so dark and dirty that detail cannot be got in any other way. A yellow-green and a set of yellow filters are sometimes helpful in photographing landscapes to get detail in the blue skies.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Printing. Printing the negative, if everything has gone according to plan, is straightforward. If, however, it has been impossible to avoid reflections, the resulting dense areas on the negative may be rubbed down with metal polish or reduced with ferricyanide. And if parts of the negative print up too dark, tissue paper cut exactly to the shape of the thin patches may be put on the ground glass of the printing box under the negative, or the thin parts may be held back in the usual way during enlarging. These controls should not be allowed to falsify tones too much.

Care must be observed in finishing the print not to do any spotting that removes part of the picture. With good technique, it should not be necessary to do any finishing at all.

Slides are another form of reproduction in great demand by lecturers on art history. The best method to get slides of first-class quality is to make them through a camera on to a lantern plate. The negative is set up in a frame with an even light behind it and photographed in the normal way.

Infra-red, ultra-violet, X-ray and micro-reproduction of pictures all have their uses for the art historian and restorer, but this work is a branch of scientific photography and lies outside the scope of the photographer who simply wishes to make a good reproduction of a painting or drawing. V.C.W.

Colour. If colour transparences are required, colour reversal film should be used. When colour prints are wanted, negative colour film should be used, and although this type of film is more accommodating to different kinds of lighting, the best results are obtained when exposures are made under the conditions for which the film is balanced. "Universal" negative colour films are usually balanced for clear flashbulbs (about 4,000° K.), and a Wratten 82C filter is appropriate when the original is lit by tungsten lamps. Weak colour-negatives will not give good prints, so it is safer to err on the side of over-exposure. For many subjects negative colour film as intended for normal photography is perfectly suitable, but certain subjects containing areas of pure white or lettering may appear to lack sparkle when the colour prints are made. The low contrast required for good tonal rendering of the picture as a whole then allows white to become a little degraded. In such cases it may be advisable to use an internegative type of colour film, especially made for copying coloured originals, transparencies or prints. The characteristic curves of internegative emulsions steepen considerably at the highlight end of the scale and excellently clean colour prints can be made from a properly exposed internegative. The production of an internegative requires the use of a preliminary

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

test-chart of a range of neutral greys, from a dense black to pure white paper, upon which one or more trial exposures are made. After processing, the tricolor densities are measured with a densitometer and their curves drawn against the reflection-densities of the test-chart. The correct relative exposures which place the highlights upon the steeper portion of each curve can then be deduced with any correction-filtering which may be seen to be required. This may seem laborious, but important subjects will merit the extra trouble.

Pigment Characteristics. In Nature, colours may sometimes have a high degree of purity (i.e. a low proportion of rays of wavelengths outside the band of the predominant hue). This is because phenomena such as refraction, diffraction and polarization tend to be highly selective in the way in which different wavelengths of light are emitted.

Ordinary pigments, however, act upon the light which falls upon them simply by absorbing much of the light of wavelengths other than those of the principal colour. The efficiency of this is low in that the purity, saturation and brightness of the best of pigments are imperfect. In other words, some of the wavelengths which should be entirely absorbed are, in fact, reflected whilst wavelengths which should be reflected are partially absorbed. Hence, even the brightest blue pigment will reflect some yellow, orange and red rays and at the same time fail to reflect more than about 40 per cent of the blue rays. Blue pigments are particularly poor in this respect, but to some degree this is true of all artists' colours, particularly when ground in oil or varnish medium. The result is an inability of mixtures of pigments to match exactly certain colours in Nature. Expert painters overcome this by clever juxtapositioning of colours or manipulation of the technique itself, to produce an illusion of greater brilliance and saturation of colour than is there in fact. This may be readily proved by holding a colourman's sample chart of tube pigments close to any oil-painting.

So paintings are nearly always a compromise in faithful colour rendering, even though the painter may choose from a hundred prepared pigments—and whether he was conscious of this at the time or not. When the photographer comes to reproduce the painting, the limitations go further. Firstly, all practicable processes of colour photography employ only three channels of colour analysis, plus, in certain work, a grey channel to reinforce the light and shade values.

These are achieved either by filtering or by selective sensitization of a three-layer colour film. In either case there is some unwanted reaction to red values by the blue and green channels. Blue is slightly recorded in the red and green channels and some green rays are recorded in the red and blue channels.

These faults of recording can be corrected by independent masks, for work which merits the very time-consuming use of such techniques. In certain negative colour processes integral coloured masks, which are automatically formed in one or more image layers during processing, substantially reduce faults due to defects of recording and deficiencies of the dyestuffs which form the three negative images. In reversal transparency processes, however, such automatic masking is not possible because the colour film upon which the exposure is made forms also the final positive. In such cases and in any other process where masking is not incorporated the degradation of colour rendering will be the sum of any faults of selectivity between the three channels and the dyes or pigments which form the ultimate print or transparency.

Dyes produce visual colours by selectively absorbing wavelengths other than those of their own colour. Most positive colour processes nowadays use yellow, magenta and cyan dyes which should in theory completely absorb blue, green and red respectively.

In practice dyes do not behave in this ideal way and have to be balanced one with another in purity and exposure-density response. As a result complete fidelity in reproduction is impossible; some degradation is inevitable. In making their compromises, colour-film makers aim to record neutral greys fairly accurately, together with plausible flesh-tones and foliage-colours. But colours which cannot be matched by varying combinations of density of the three primaries in a given system (i.e. the cyan, yellow and magenta dyes of the film) cannot be accurately reproduced.

In graphic arts techniques, gross errors are often reduced by retouching intermediate images or by correction-masking; but in the end the limitations are imposed by the defects of the inks or dyes used for the ultimate printing.

Fortunately, many works of art can be reproduced without such faults being very obvious, particularly when the reproduction is smaller in size than the original. Subjectively, the eye tends to consider colours to be brighter and more pure when the image becomes smaller and this offsets the reproduction losses to a large degree.

Fluorescing Agents. In recent years, fluorescing agents have been introduced to the textile and paper trades to produce so-called "whiter than white" effects. These substances absorb ultraviolet radiation present in the illumination, and re-emit it as visible light. This can lead to a treated sample of white material reflecting 15 to 20 per cent more visible light than an untreated one, giving the illusion of greater brightness.

Unfortunately, the extra light may not be equally distributed over the visible spectrum. Though a black-and-white photograph of an artist's drawing or painting may be quite satisfactory, so long as he has not made corrections with ordinary white pigment, a colour

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

film may record the particular tint of the fluorescing substance quite differently from any pigment whites. Even in monochrome, any retouching, with visually matching white paint, shows up.

The only cure is to photograph such paintings with strict exclusion of ultra-violet rays. Ordinary household lamps of low wattage and general purpose floodlamps give off too little ultra-violet, in relation to the longer wavelengths, to cause trouble. But sunlight, electronic flash, arc-light, high-efficiency tungsten lamps and most kinds of fluorescent and discharge-lamps used in photography all require UV-absorbing filters in front of them. Even photoflood lamps emit enough ultra-violet to cause trouble when highly fluorescing substances are present in the original. (A camera-filter will not cure such trouble as the fluorescence has already occurred in the original before the light reaches the camera lens).

Old drawings and paintings and modern ones for which only the finest hand-made papers, panels or canvasses have been used, rarely contain fluorescing substances. The UV-absorbing nature of the binders in oilcolours would destroy the effect even if present. A number of modern pigments formed from *dyestuffs*, however, fluoresce when exposed to a source of ultra-violet radiation. For display and showcard work this effect is deliberately exploited in "Dayglow" type paints. In cheaper decorators' colours and whenever the illusion of great brilliance is more important than other qualities, such fluorescence is welcome, even though it cannot be reproduced by photographic means. In some cases, the fluorescence inherent in a particular dye may be of a different colour from that which it normally exhibits. The cure, as in the case of fluorescent papers and textiles, is to exclude ultra-violet rays from the original when photographing it, whether in monochrome or colour.

The presence of fluorescing substances may be detected by exposing the subject to the light from a "black-light" UV-lamp in a darkened room. An unmistakeable glow shows up the offending areas. Artists who are preparing work especially for reproduction owe it to their clients to use only art-boards free from "brightening agents" and either to use only the finest artists' quality water colours of the traditional kind, or to submit the poster and designers' colour charts to this test before admitting them to their studio. The cost of retouching and correction of defects in process engravers' establishments is considerable. Process engravers themselves, because of the especially UV rich illumination which they prefer, owe it to their clients to test originals before copying and to employ light-filtering where this is needed. J.V.

PALLADIOTYPE. Printing process introduced *c.* 1916 capable of very delicate tone rendering. Special paper was used and the final image consisted of palladium. The process was very similar to platinotype.

See also: *Printing processes (obsolete).*

PAN AND TILT HEAD. Tripod attachment which permits the camera to be turned around its vertical axis and to be tilted in a vertical plane. Elaborate pan and tilt heads are used mainly in cinematography where they permit smooth movement of the camera during shooting, but are equally useful for accurate setting up in certain fields of still photography. The head may carry scales showing the horizontal and vertical rotation in degrees.

See also: *Camera supports.*

PANCHROMATIC. Sensitized materials with a response to all colours of the visible spectrum, including the red rays.

See also: *Infrachromatic; Negative materials; Ordinary emulsion; Orthochromatic; Orthopanchromatic; Spectral sensitivity.*

PANCHROMATIC VISION (P.V.) FILTER. Viewing filter through which the scene appears more or less in monochrome as a panchromatic emulsion would reproduce it. The effect of using filters in front of the lens can be approximated by adding them to the P.V. filter.

See also: *Tone rendering.*

PANNING. Term often used to indicate the swinging of the camera following a moving object, in order to record a sharp image.

See also: *Swinging the camera.*

PANORAMA. Picture that presents a continuous view of the landscape. In practice such comprehensive pictures are generally built up from a series of separate photographs covering the horizon, in slightly overlapping sections. There are also special panoramic cameras designed to scan any arc of the horizon and record the picture on a single continuous length of film.

Precautions. When a normal camera is used for making panoramas, certain special precautions must be taken or the adjacent photographs will not dovetail into one another without leaving a visible join.

(1) The camera must be mounted on a tripod. This is to make sure that all the photographs are taken from the same viewpoint. If the viewpoint moves between one exposure and the next, the perspective of the two photographs is no longer the same, and it is not possible to find a common boundary for joining them.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PANORAMAS. Top: In taking a panorama the camera should be firmly mounted, and rotated through a fixed angle (preferably about the front nodal point of the lens), after each exposure. Successive views must overlap to permit matching up later on. Centre: The camera must be mounted absolutely level, otherwise the horizon line will appear to curve down (camera pointed up) or up (camera pointed down). Bottom: One way of hiding the joins in the assembled print is to follow the outlines of prominent features of the view in cutting.

(2) The camera should preferably be mounted on a special head marked off to show the successive camera positions (for the particular lens in use) that will cover the horizon in sections with a suitable overlap between each section.

(3) The camera must be absolutely level—i.e., the focal plane of the lens must be vertical—or the adjoining edges of the separate pictures will not match. For this reason many of the panoramic heads incorporate a spirit level.

(4) If the horizon is to appear above or below the centre of the picture, the adjustment must be made by using the rising and falling front, if the camera has one, or by trimming the prints; it cannot be done by tilting the camera.

Panorama Tripod Heads. It is possible to take panoramas with the camera mounted on an ordinary tripod head by loosening the clamping screw and turning the camera through the required angle between exposures. After taking the first exposure looking at, say, the extreme right hand side of the view, the camera is swung around until a point on the horizon that previously appeared just inside the left hand edge of the first exposure is just inside the right hand edge. The second exposure will then overlap the first by a sufficient margin. Further exposures are made in the same way until the whole of the required field has been covered.

Special tripod heads are available for taking panoramas. These make it easy to turn the camera through the exact angle between exposures. The head generally incorporates a spirit level and is in two parts, a fixed base which screws on to the top of the tripod and a swivelling head which can be locked in any position. A scale ring graduated from 0° to 360° around the base shows how far the camera has been turned. With a lens taking in an angle of, say 50°, the head would be set at zero with the camera at the right hand end of the picture and for subsequent exposures moved to 45°, 90°, 135°, and so on, covering the picture area with an overlap of 5° between exposures.

There are special panorama heads which indicate the correct position for each exposure by an audible click. These are designed to work with a lens of a particular focal length, or they may have a set of interchangeable rings which suit a number of different lenses. Automatic heads of this type cut down the time between exposures and so make it possible to deal with subjects where there is some movement—e.g., of clouds or traffic—in the scene.

Suitable Subjects. The subject chosen for a panorama should have plenty of variety; mountains, docks and riverside buildings seen from the opposite side of the river and famous views are the right sort of material. Scenes with a straight, unbroken horizon line are generally not worth taking. Moving objects call for extra care to see that they do not appear on two sections of the same panorama. There is an unavoidable loss of time between one exposure and the next, and in that time a moving object can pass from one section into the next. On windy days, when the clouds are moving and changing shape quickly, it may be impossible to make a satisfactory panorama showing clouds.

Vertical Panoramas. In making a vertical panorama, the camera is mounted on a tripod fitted with a tilting head and swung in a vertical arc. Subjects for this type of panorama are rare because the whole field can generally be included in a single exposure with a lens of normal focal length. The view from the top of a cliff that falls vertically away from the camera makes a suitable subject if, for instance, there are streets and houses in the valley immediately below the camera and mountain scenery facing it.

Mounting Panoramas. Provided the prints are made from correctly made negatives there is no difficulty in joining up and mounting adjacent pictures. The prints should be first arranged side by side and one lapped over the other until the edge of the upper print registers with the scene in the lower. The overlapping edge of the top print is then lightly stuck down on the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

lower, preferably with india rubber solution.

When dry, both prints are cut through together down a line midway between the overlapping edges. This means that when the prints are mounted edge to edge, the two sides of the join will register perfectly and be almost invisible.

An even less conspicuous way of matching up is to follow prominent contours of the scene when cutting one edge (e.g., the left-hand one) of each print (except the left-hand print of the series). Provided these contours all lie within the overlap area of the adjoining print, they will tend to hide the join.

When mounting, the edges should be sandpapered down from the back as thin as possible before assembly. The base of the one print and the surface of the edge area of the adjoining print are then smeared with rubber gun, and the top print placed in position. Any excess gum can be rubbed off the surface when dry. P.J.

PANORAMIC CAMERA. Special type of camera for making a continuous record of a wider section of the horizon than could normally be photographed in a single exposure. The lens scans the view from side to side and exposes a long narrow strip of film through a moving slit.

In practice the lens is made to rotate about its rear nodal point together with the whole camera on a tripod head, while a governor-controlled motor winds the film past the slit from one spool to the other. The film movement is carefully synchronized with the camera rotation, so that the image remains in effect stationary with respect to the film. The film itself is supplied in special lengths to suit the camera. With a suitable tripod mounting, such a panoramic camera can cover a complete circle of 360°.

PANORAMIC CAMERA. The lens covers only a small field, but pivots about its rear nodal point, thus "seeing" different parts of the view in turn. The film is wrapped round a curved drum which the image scans from one end to the other.

355 DEGREE HORIZON CAMERA. Top: Section. Bottom: Top view. The film from the feed spool runs round a drum and from there on to the take-up spool. A series of windows separated by diaphragm blades takes in image-forming rays over virtually the full circle and directs them via a special hemispherical lens on to the 35 mm. film in the image plane. A, film spool. B film (shown by broken line on lower diagram). C, window (one of a ring). D, concentric hemispherical lens. E, field flattening lens. F, diaphragm blade.

Cameras of this type are also used for taking long formal groups. The total exposure time from one end of the picture to the other is in the region of 10–15 seconds, though the effective exposure of each point in the picture may be around 1/10 second. This could be varied by making the slit narrower or wider, but in practice a simpler method of exposure control is adjustment of the aperture.

In the case of a group shot the whole group should keep still while the camera is running. Double exposure stunts are, however possible by one or two members at the first extreme edge running round the back to the other end of the group as soon as the camera view has passed them.

Special panoramic cameras have also been developed which cover a view up to 355° in a single simultaneous exposure on a curved strip of film with a special optical system.

PANTONE. Special type of dry litho photomechanical reproduction process developed from about 1924 onwards by Ronald Trist. This process was lithographic in principle but printed without water on ink-repelling areas.

A sheet of copper or, more commonly, copper-plated steel, was plated thinly with chromium. An acid resist image in line or half-tone was formed on the chromium which was then etched away down to the copper base in the non-image areas. The bare copper was silver plated and then treated with mercury which

amalgamated with the silver, after which the plate was ready for the printing machine.

Printing ink will not take on a mercury-silver amalgam, but it takes very well on chromium; thus the plate could be rolled up with printing ink and used for direct or offset printing.

At its inception, Pantone appeared to be most promising. It would print on litho or letterpress machines, and the inventor devised many ingenious and useful developments of the basic principle; but it failed for such reasons as the tremendous printing pressure necessary on letterpress machines, the difficulty of replenishing the mercury by addition to the ink, objection to the poisonous nature of the mercury, litigation over patent rights, and scarcity of mercury. The commercial development of chromium plating was prompted by its use in the Pantone process.

PAPER GRADE. Most types of development paper are manufactured in a range of numbered grades. Each number corresponds to a particular type of image contrast—e.g., hard, normal, soft. Although there is no general agreement between manufacturers, most tend to favour five grades—No. 1 (Soft), No. 2 (Normal), No. 3 (Hard), No. 4 (Extra Hard) and occasionally, No. 5 (Ultra Hard). It does not follow that the same grades of different manufacturers all produce the same contrast.

By selecting paper of the correct grade it is possible to produce acceptable prints from negatives with contrast scales ranging from very soft to very hard.

A normal negative will yield the best print on a normal paper grade. However, a soft and flat negative will require a hard paper grade to put adequate brilliance into the print, similarly a contrasty negative needs a soft paper grade to record the extremes of th etone scale and produce an acceptable print.

PAPER HOLDER. On a horizontal enlarger the easel and paper holder are combined, but on a vertical enlarger the paper holder is usually a separate accessory.

Adhesive Holders. One of the earliest devices for holding down the paper was a shallow tray filled with a glycerin-gelatin jelly. The paper was simply pressed on to the surface of the jelly and held by adhesion. Nowadays the same effect can be produced by a double-sided adhesive sheet. One modern enlarger with a pressed steel baseboard is supplied with two magnetized strips which hold the paper firmly by its edges. Nowadays, however, most photographers favour the type of paper holder which is also a masking frame. These are made in both fixed and adjustable types and by virtue of the fact that they hold the paper by its edges, invariably give a print with white margins.

Masking Frames. The fixed size masking frame, which is commonly made in postcard and two-on postcard sizes, is simply an inverted shallow box the same size as the paper with a further box which fits neatly over it. The bottom of the outer box is cut away to form the picture aperture with a narrow rebate $\frac{1}{8}$ or $\frac{3}{16}$ in. wide all round. The printing paper is placed on the lower half, and the upper section is fitted over it. This holds the paper flat and leaves it exposed except for the margins.

Masks of this sort are made in both metal and moulded plastic.

Adjustable Types. Adjustable masking frames usually consist of either a metal or wooden baseboard to which is hinged an open frame of metal of square section which carries two metal masking strips. These strips are made to slide along adjacent sides of the frame so that they can be adjusted to enclose a rectangular picture space of any dimensions up to the full size of the holder. When a sheet of paper is placed between the board and the frame, the frame itself masks the paper on two adjacent edges, and the adjustable strips mask the remaining two.

The width of the white border is fixed by the width of the metal frame, and the adjustable strips are set so that they mask off the same width along their sides of the paper. Some types are made that permit actual adjustment of the border width. The paper is located under the mask by pressing it against two stops as the mask is lowered.

Masking frames for enlargements without white border frequently use a hinged glass plate in place of the frame, to hold the paper flat. Locating stops at the side of the frame help in positioning the paper. The glass plate must naturally be kept absolutely clean and free from dust, as well as from scratches. The glass itself is a flawless sheet of flat plate glass.

Borderless enlargements can also be produced on a simple board with two adjacent raised edges acting as positioning guides.

Exposure Control Systems. Advanced paper holders for commercial printing and enlarging incorporate a photo-multiplier system that measures the light coming through the paper in the holder and is used to control enlarging exposures. The surface of the holder is in this case a translucent sheet of glass, with one or more photo-multiplier cells underneath it. These integrate the light coming through (in other words measure the average light intensity) and thus automatically allow for different negative densities and different degrees of enlargement. The photo-multiplier cell usually controls a relay that switches off the enlarger light (the cells having been activated by switching on) when a predetermined amount of light has reached the photo-multiplier cell.

The exposure control must be calibrated according to the translucency of the paper base and the paper speed; a further adjustment is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

also necessary for different print sizes. This arises because the photo-multiplier cells measure the light coming through a given area of the paper holder surface; if this area is reduced by masking down for smaller print sizes, the light reaching the cell naturally also decreases (although the light intensity on the paper may remain the same).

Similar automatic paper holders for colour enlarging may incorporate three sets of photo-multiplier cells with red, green and blue filters respectively in front of them. Each cell then monitors the appropriate colour component, and controls the exposure by light of that colour, or the movement of filters in the enlarging lamp house. G.W.A. & L.A.M.

Book: *Enlarging*, by C. I. Jacobson (London).

PAPER NEGATIVE. One of the cheapest forms of negative material consists of a negative emulsion coated on a paper base, known as negative card.

Many cameras produced for use by "while-you-wait" photographers are designed for this material. The card is loaded into sheaths and exposed in the camera in the normal way. After processing it can be printed in a number of ways: by being re-photographed in the original camera on to a similar card; by treating it with oil to make it translucent and then printing by transmitted light; by printing it by reflected light in a special enlarger working on the principle of the episcope; or by reflex printing. The last method is commonly used in document photography, especially in office copying machines.

Instant-picture cameras based on transfer diffusion also use a paper-based negative. This, however, is discarded after processing, where its function is to produce the positive image by transfer.

Paper negatives have been favoured by pictorialists and portrait photographers because they are so much easier to retouch than films or plates. It might sometimes be worth while to make an enlarged paper negative from a miniature negative that calls for retouching. In this way any number of prints can be made from the finished negative.

See also: *Supports for emulsions; While-you-wait photography.*

PAPERS

The final form of a large proportion of photographic records and pictures is the paper print. It is produced in most cases by exposing a sheet of sensitized paper in contact with a negative, or to the image of a negative projected by an enlarger.

The main types of paper for general photography are development papers which form a latent image that must be developed before it becomes visible. These are used in pictorial, technical, commercial, and professional photography. Special emulsions in this group are used for document photography and recording.

Another type of paper which used to be widely popular half a century ago is daylight paper. This forms an image on direct exposure, and needs no development. These papers are known as either print or printing out papers and were formerly employed for pictorial photography, but are now almost entirely confined to making proofs; within this type also come a number of specialized materials for plan-copying and similar purposes.

DEVELOPMENT PAPERS

Development papers vary in three important respects:

(1) Type of emulsion—i.e., chloride, bromide, chlorobromide, etc. (This also governs the development characteristics and image tones obtainable.)

(2) Contrast range—i.e., soft, normal, hard.

(3) Physical characteristics—i.e., thickness, surface finish, colour, etc.

The sensitive layer of most development papers consists of silver chloride, silver bromide, or a mixture of the two, in a gelatin emulsion. The relative proportions of silver chloride and silver bromide determine both the sensitivity and the image tone of the paper. Certain papers also contain a small proportion of other salts such as silver iodide.

With one or two exceptions—e.g., variable contrast papers—printing papers are not colour-sensitized. They are sensitive only to blue and violet rays.

There are four types of emulsion commonly used for coating development papers: silver chloride for contact papers, slow chlorobromide for warm tone contact papers, silver bromide for enlarging papers, and fast chlorobromide for warm tone enlarging papers.

Silver Chloride Papers. These are papers in which the emulsion contains silver chloride only.

The sensitivity of these papers is comparatively low, and they are generally suitable only for contact printing in a printing frame or printing box. Because of this limitation they are therefore referred to as contact papers, or by their older name of gaslight papers.

They are so slow to artificial light that they may be handled by subdued artificial light, or by a bright yellow safelight.

Chloride papers give blue-black tones in a metol-hydroquinone developer and take about 45 seconds at 65–68° F. (18–20° C.) to develop.

Slow Chlorobromide Papers. These papers have an emulsion that consists mainly of silver

chloride, with a smaller proportion of silver bromide.

They are up to ten times as sensitive as silver chloride contact papers, and are generally suitable for contact printing, although they are sometimes used for enlarging.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

As silver bromide is more sensitive than silver chloride, these papers must be handled under an orange or yellow-green safelight.

Slow chlorobromide papers give warm black tones on development in a metol-hydroquinone developer. They can, however, produce brown-black to warm brown and even reddish images by over-exposure followed by development in a dilute and heavily restrained developer.

Silver Bromide Papers. These papers are known as plain bromide papers. The emulsion contains only silver bromide with perhaps a trace of silver iodide.

Bromide papers are the most sensitive of all printing materials (100 to 1000 times as sensitive as chloride contact papers). They are mainly used for making enlargements where the intensity of the printing light is generally very much less than for contact printing.

As all bromide papers are sensitive enough to be fogged by even weak white light, they must be handled only by olive-green or orange darkroom illumination. Certain bromide papers are double coated and slightly colour sensitive. These can only be handled safely by the light of an orange safelight.

Bromide papers give pure black prints on development in metol-hydroquinone. Development usually takes about 1½–2½ minutes at 65–68° F. (18–20° C.).

Fast Chlorobromide Papers. Fast chlorobromide papers have an emulsion that contains mainly silver bromide, with a smaller amount of silver chloride and sometimes a little silver iodide. These papers are nearly, though not quite, as sensitive as ordinary bromide papers. They are mainly used for making enlargements, and need about 1½ to 4 times as much exposure as bromide papers.

Some fast chlorobromide papers are sensitive to green light as well as to blue and violet. An olive-green darkroom light is therefore not always safe enough; orange is better.

Fast chlorobromide papers give warm-black image tones on direct development in metol-hydroquinone paper developers. The usual development time is about 2–3 minutes at 65–68° F. (18–20° C.). Prolonged development of over-exposed prints in a dilute and heavily restrained developer gives warm brown and sepia tones as it does with the slow chlorobromide emulsion. The range of tones available is, however, not as wide with the slow chlorobromide emulsions.

Automatic Development Papers. Papers intended for automatic roller processing machines frequently incorporate also hydroquinone or another developing agent in the emulsion. During development the paper then passes through an alkaline activator bath which in conjunction with the developing agent develops the image on the spot within a few seconds. Papers of this kind may have either chloride or bromide emulsions.

PAPER GRADES. Top: A, *negative with long scale of tones from black to transparent.* B, *printed on hard paper;* C, *on medium paper;* D, *on soft paper. These papers reproduce respectively a short range, most, or all of the negative tones, spreading them from black to white.* Centre: E, *negative of short scale of tones.* F, *printed on hard;* G, *on medium;* H, *on soft paper. The negative tones are increased in contrast, reproduced correctly, or flattened respectively.* Bottom: I, *negative with long scale of tones.* J, *printed on hard paper to secure tone separation and highlight detail at the expense of the shadows.* K, *exposed to secure shadow detail at the expense of highlights.*

Contrast Grades. Most development papers are made in several contrast grades. A range of such grades is necessary so that the photographer can select the most suitable to make the best possible print from every type of negative—from soft to hard.

The paper grades are usually classified by each maker according to his own ideas. There is as yet no standard system, but most of those in use at present conform broadly to the following scale:

No. 0: extra soft
No. 1: soft
No. 2: normal, or medium
No. 3: vigorous, hard, or contrasty
No. 4: extra vigorous, extra hard, or extra contrasty
No. 5: ultra vigorous, ultra hard, or ultra contrasty.

A particular grade of paper made by one manufacturer does not necessarily correspond to a paper carrying the same number or

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

description but supplied by another manufacturer. Grade 2 of one maker may well correspond to grade 3 or grade 1 of another brand.

The "normal" or "medium" grade of paper is accepted as being the one that gives the best print from a good average negative.

A soft paper with the same negative would give a flat print without much tone gradation. The whole picture would be rendered in fairly similar tones of grey with no real blacks, and no really light highlights.

A hard paper would give an over-contrasty print in which all the light tones would be blank white paper and the darker parts would be areas of solid black.

Compensating for Negative Shortcomings. A soft grade of paper can be used to tone down a very contrasty negative and produce a fairly normal print. And one of the more contrasty grades of paper can be used to compensate for lack of brilliance in a very soft negative and again allow a normal print to be made. In contact printing and enlarging the contrast grade of the paper is matched in this way to the contrast of the negative; the softer the negative, the harder the paper grade required, and vice versa.

Surfaces. The "surface" of a paper is a combination of its texture and its finish.

Its texture may be smooth, fine grained, or rough. In addition, there are several artificial surfaces which are made to resemble fabrics like silk, rayon, canvas, etc.

Its finish may be glossy, semi-glossy (described under various names such as semi-matt, half-matt, velvet, lustre, etc.) and matt.

A glossy finish can only be produced in conjunction with a very smooth surface texture. A glossy print can, in addition, be glazed after processing to give a mirror-like shiny surface. A matt finish must also have a very smooth surface texture; but a semi-glossy or lustre finish may be used for every type of texture.

Enlarging papers and, to a lesser extent, contact papers, are made with a variety of surfaces. This variety enables the photographer to enhance the artistic effect of a picture by choosing a suitable paper to match the mood or character of the subject.

The Paper Base. The paper support that carries the sensitive layer may be either white or tinted, generally ivory or cream. Some modern white-base papers incorporate a fluorescent dye to increase the luminosity of the whites.

Most papers are made in a range of base thicknesses; the thinnest is light-weight (air mail), the thin standard base is single-weight, and the thick standard is double-weight. The thickest base of all is treble-weight, which is a comparatively heavy card.

Some types of paper base may be translucent, especially for document copying purposes. These are generally thin bases.

Papers intended for high speed processing often have a waterproof base. This is to minimize the absorption of solutions and so speed up the drying.

Printing paper manufacturers have their own code letters and figures which they print on the pack to indicate the contrast grade, surface, base tint, and paper thickness of the contents.

Choice of Papers. The selection of a print surface and paper tint for any particular print is largely a matter of taste. Prints intended for reproduction are an exception; they are always supplied on glossy or glazed white-based paper.

Apart from this special requirement, the photographer can generally contribute something to the pictorial appeal of his work by selecting a paper with the right characteristics.

A cream paper base may help to impart a suggestion of warmth and sunniness to the picture, and a warm-tone image tends to enhance the impression. Traditional or dignified types of subject, as well as character portraits, often look better on cream or ivory tinted papers.

Essentially black-and-white subjects—e.g., snow, mountains, machines—are generally handled better by a white based paper.

The smoother the paper surface, the more it shows up fine image detail. The smoothest glossy surface, particularly when glazed, is therefore specially suitable for scientific and technical subjects, small contact prints and prints for copying and reproduction.

A rough surface breaks up empty image areas, so it livens up broad subjects and big enlargements where there is comparatively little fine image detail. And rough paper also helps to hide graininess in big enlargements.

Artificially embossed surface textures such as rayon, silk, etc., have a similar effect.

Maximum Tone Range. The paper tint, image colour, and surface, affect the visual tone range of the print.

The visual range is narrower when the paper base is tinted than when it is white, because the tint darkens the lightest tones. A tinted paper surface reflects only 30–50 per cent of the light falling on it, compared with up to 90 per cent for a really white surface.

A warm tone image has a shorter range than a pure black one because it can never reproduce such deep shadows.

Semi-matt and rough surfaces scatter the light falling on them. This also increases the visual brightness of the shadows and so narrows the available range of tones. (This explains why matt prints often appear to lack brilliance and why they look brighter and more contrasty when they are wet than they do after they have dried.)

The maximum visual contrast is given by a pure black-and-white glazed glossy print. The white is the brightest possible, while the smooth surface and black tones ensure low reflectivity in the darkest image areas.

But the photographer who goes in for unusual

paper surfaces runs the risk of distracting attention from the subject matter of his photograph. Most photographs in fact look best when printed on a non-committal, semi-matt, print surface, on white or ivory-white paper.

CC-0. Agamnigan Tupik Digital Preservation Foundation, Chennai

Document Copying Papers. Papers for office and document copying purposes have special characteristics for the job they are required to do. They are mostly slow in speed and ultra-hard in contrast. Papers for office copying machines are frequently intended for reflex printing and can be handled by ordinary subdued daylight or artificial light. Mostly they are silver chloride papers and may incorporate a developing agent in the emulsion for rapid processing systems. Faster emulsions are also available for enlarging microfilm negatives; papers of this kind have to be handled in a darkroom by appropriate safelight illumination.

Some document copying processes follow special systems and may use pre-fogged papers (which yield a positive image from a positive on exposure to yellow light which destroys the existing latent image) or a diffusion-transfer process.

Document papers are mostly coated on a lightweight paper base and are matt surfaced. Thicker paper bases are also available, as well as translucent bases. The latter have a structure reminiscent of grease-proof paper, and are intended for making document copies that are to serve as master negatives or positives for subsequent mass printing by dye-line and similar processes.

COLOUR PAPERS

Papers for making colour prints are mainly of two types: positive and reversal.

Positive Colour Papers. These are intended for making colour prints from colour negatives. They invariably work on the subtractive colour principle and consist of three sensitive layers sensitized to blue, green and red light respectively. The layers also incorporate complementary colour couplers. As a result the blue-sensitive layer yields a yellow image on development in a colour developer; the green-sensitive layer yields a magenta image and the red-sensitive layer a cyan image. The three layers record the colour components of the negative image and reverse both the tone and the colour values of the latter.

Sometimes the sensitization of the three layers of a positive colour paper is specially matched to the characteristics of the dyes in the colour negative material of the same manufacturer. In extreme cases the nominally red sensitive layer may for instance be sensitized mainly to infra-red and the deep red end of the spectrum. This tends to improve colour separation and reproduction.

Processing involves colour development, a stop bath and bleaching of the silver image plus fixing out of all the silver salts. Manufacturers usually issue specific instructions and processing kits for colour papers of their own make; universal colour processing formulae for positive colour papers also exist. Usually the printing procedure requires some modification when non-standard formulae are used. In any case development time and temperature in the colour developer are very critical.

The exact colour balance of the print is also controlled deliberately by adjusting the colour of the printing light with the aid of appropriate filters.

Reversal Colour Papers. These yield a positive colour print from a positive transparency and require reversal processing. This resembles the procedure for reversal colour films. The processing solutions and procedure must be accurately matched to the particular make of colour paper employed; the manufacturer issues full instructions and kits where the paper is released for processing and printing by photographers. (Some reversal colour papers are released only to colour finishing laboratories appointed by the manufacturer.)

The structure of the reversal colour paper is very similar to that of a positive colour paper, and formation of the colour image proceeds in the same way as in the case of the reversal colour film. Colour rendering can be controlled within limits by modifying the printing light with filters.

Special Colour Papers. Some types of colour paper, both of the positive and of the reversal kind, work by a dye-destruction process. Here the paper already contains finished dyes in the three emulsion layers; these dyes are destroyed image-wise during processing and so leave a dye image after removal of the developed silver image and silver salts.

Special colour papers, sometimes with only two colour-forming layers, are also used in certain recording applications.

DAYLIGHT PAPERS

At one time daylight papers were very widely used for making positive prints. They form a visible density directly on exposure to actinic light, whereas development papers do not show the effects of exposure until treated with a developer.

The sensitivity of daylight papers is very much less than that of development papers, and they are nowadays very little used except in cases when their slow speed and special characteristics are an advantage.

Recording Papers. The main current use of "daylight" papers is to record traces of moving spots of light, for example as reflected from the mirror of a galvanometer or other recording instrument. The paper there moves continuously past the location of the moving light spot; the vibration of the latter thus exposes a trace on the moving strip of paper. This image is visible immediately after the exposure, but

darkens on further exposure to a controlled light source.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Printing-Out Papers. Print-out papers of the more old-fashioned kind are usually coated with a sensitive emulsion of silver chloride in gelatin or collodion. Their sensitivity is so low that they may safely be handled in ordinary artificial light, and even in subdued daylight.

Print-out papers usually give a reddish image which is toned with gold or platinum before fixing to produce sepia to brown prints. Ordinary print-out papers used to be employed by professional photographers for proof prints.

Some so-called self-toning daylight papers incorporate the gold toning salts in the emulsion. Such papers tone automatically in the fixing bath and do not therefore need a separate toner.

Special Daylight Materials. Other daylight printing materials rely on the sensitivity of either ferric salts or of colloids like bichromated gelatin.

In iron printing papers the action of light reduces ferric salts to the corresponding ferrous compounds. These in turn can be made to form usable images in a number of ways.

In the obsolete platinotype and palladiotype papers, the ferrous compounds reduced platinum or palladium salts to the corresponding metals, thus producing permanent platinum or palladium images in attractive tones of brown.

In the same way the ferrous compounds can be made to react with silver salts to form a black silver image (Kallitype process).

A blue image can be produced by making the ferrous salts react with potassium ferricyanide to precipitate Turnbull's Blue as in blue-print papers.

In certain types of blue-print paper the images are formed from the unexposed ferric salt. These papers therefore give negative prints from negatives, and positives from positive transparencies.

Iron printing out materials are mostly used for photomechanical reproduction of drawings.

Bichromated colloid (gelatin, gum, glues) materials make use of the tanning action of bichromates on colloids that have been exposed to light. This renders the gelatin or gum insoluble in the exposed parts of the print. The rest remains soluble and can be washed off with hot water to leave a relief image.

If the gelatin coat is coloured with a pigment a visible pigment image is left after washing. This is the principle of the carbon and carbro processes.

The tanned gelatin image also possesses the property of taking up greasy inks in proportion to its degree of exposure and consequent hardening. This method of pigmenting the image is the basis of the oil (and derived bromoil) processes.

Bichromated colloids are extensively used in photo-engraving to produce etching resists and other images by the action of light.

Other daylight printing materials utilize the action of light on certain diazo compounds. After exposure, these compounds lose their ability to produce dyes by coupling. So by treating the material with suitable couplers after exposing it under the negative, the unexposed parts of the image form a dye image but the exposed parts remain unaffected. This produces a negative image from a negative and a positive from a positive. Like blue-print papers, diazotype materials are mainly used for photomechanical reproduction. L.A.M.

PARA-AMINOPHENOL. (Free base) 1-amino-4-hydroxy-benzene. Developing agent used in certain concentrated developers.

Formula and molecular weight: $NH_2C_6H_4OH$; 109.

Characteristics: White crystalline powder.

Solubility: Slightly soluble in water at room temperature. Freely soluble in alkaline solutions, especially caustic alkalis. Very slightly soluble in sulphite solutions.

PARA-AMINOPHENOL HYDROCHLORIDE. 1-amino-4-hydroxybenzene hydrochloride. Developing agent.

Formula and molecular weight: $NH_2HClC_6H_4OH$; 145·5.

Characteristics: White powder.

Solubility: Fairly soluble in water at room temperature. Freely soluble in alkali solutions. Very slightly soluble in sulphite solutions.

PARABOLIC MIRROR. Silvered glass or metal reflector of which the cross-section along the axis is a parabola. This shape has the property that if a point source of light is placed at its geometrical focus, the light reflected by the mirror will be a parallel beam. In practice, this condition can never be completely achieved because there is no such thing as a point source.

Parabolic mirrors can be used in spotlights instead of the conventional condenser lens. Parabolic reflectors also have special uses.

See also: *Mirror; Reflector.*

PARALLAX. Apparent alteration in the relative position of two objects that occurs when there is a change in the viewpoint of the observer. Also, term generally applied to the difference between two viewpoints. Because of parallax, the picture seen in the viewfinder of a camera

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

TWIN LENS CAMERA PARALLAX. Where the viewfinder is in a different position from the camera lens, it necessarily covers a slightly different view. At near distances this may lead to parts of the subject (e.g., the top of a portrait head) being cut off in the negative. Top: *Uncorrected parallax error in twin lens reflex camera.* Upper centre: *Correction by masking the finder so that it always covers less than the film.* Lower centre: *Tilting the finder lens downwards at near distances.* Bottom: *Optical wedge, deflecting finder beam for close-ups; the field covered becomes the same, though the viewpoint does not.*

is not the same as the picture seen by the lens, some inches below or to the side.

The effect is not serious at distances beyond about 6 feet, but closer than this it is necessary to allow for the difference in viewpoint. This may be done by reducing the finder field to take in only the subject area covered all the time, by correction marks in the finder, or by a mechanical shift of the finder field (with a movable mask or by tilting the finder). Automatic parallax correction systems have such a mechanical adjustment coupled with the focusing movement of the lens.

Any such compensating system can only correct for the change in image field occasioned by the parallax error; it cannot correct for the different perspective caused by the displaced viewpoint. In practice this is significant only at very close subject distances, as in macrophotography. If, for example, the camera lens is looking directly at the face of a small cube, the top of the cube will not appear in the picture but even when the viewfinder is tilted the picture will still include the top of the cube.

The only type of viewfinder free from parallax error is the focusing screen of the single lens reflex camera.

See also: *Viewfinder.*

PARALLAX STEREOGRAM. Composite positive print or transparency prepared in such a way that when viewed from a particular distance with both eyes a stereoscopic picture results. The stereogram actually consists of a combined stereoscopic pair with each picture broken up into very fine strips. The pictures are printed so that the strips of left and right hand pictures alternate. This is then covered by a suitable grid. The spacing between picture strips and grid lines, and the separation of the two, are so chosen that when looked at from the correct viewing distance each eye sees its own picture strips while its view of the other set is blocked by the grid lines.

Parallax stereograms can be printed from a normal stereoscopic pair or they can be made directly from the subject. In one typical system the original negative is made in a camera on a single plate behind a suitable grid. The camera has two lenses, separated by the interpupillary distance, and associated with a pair of prisms. The prisms bend the incoming rays of light towards the centre so that the images formed by the lenses are superimposed instead of lying side by side.

If the right and left images formed on the plate by the grid were printed in the normal way, the resulting picture when viewed would be pseudoscopic in exactly the same way as a normal stereoscopic pair printed without transposition. The correct viewing conditions are achieved, however, by simply shifting the viewing screen the width of one line to the side. This produces the same effect as trans-

PARALLAX STEREOGRAM. A grid arranged above a composite left and right eye stereogram permits each eye to see only the strips corresponding to its own view.

position in printing a normal stereoscopic pair.

The prisms used with the taking lenses in this method produce lateral inversion which is inevitable in the interest of simplicity.

The principle of the parallax stereogram has been applied to numerous stereoscopic systems the first being that of F. E. Ives, 1903. Instead of grid lines, a screen of lenticular lenses may be used, and by making numerous exposures from slightly differing viewpoints it is possible to produce a picture which presents a changing aspect when the viewpoint is moved.

See also: *Lenticular system; Stereoscopic photography.*

PARA-PHENYLENE DIAMINE. (Free base.) 1 : 4-diaminobenzene. Developing agent in fine grain developers.

Formula and molecular weight. $C_6H_4(NH_2)_2$; 108.

Characteristics: Brownish white powder.

Solubility: Fairly soluble in water at room temperature.

PARA-PHENYLENE DIAMINE HYDROCHLORIDE. 1 : 4-diaminobenzene hydrochloride. Developing agent in fine grain developers.

Formula and molecular weight: $C_6H_4(NH_2 HCl)_2$; 181.

Characteristics: White powder. More stable than para-phenylene diamine.

Solubility: Fairly soluble in water at room temperature.

PARAPHOTOGRAPHY. Collective term embracing image-forming systems based on other than the silver halide process. It covers thermography, electrophotography, photochromism, diazotypy, photopolymerization, and magnetic image recording, which are sometimes also referred to as unconventional, unorthodox, or just non-silver systems.

PARAXIAL. Term used in optics to describe rays near the optical axis of a lens. Rays farthest from the axis are termed abaxial.

PASSE-PARTOUT. Gummed material for framing pictures. The picture is placed facing a sheet of glass of the same size and the two are bound together by passe-partout binding passed around the edges. The gummed tape is sold by stationers in a range of colours together with backing, hanging loops, etc.

See also: *Framing photographs.*

PASSPORT PHOTOGRAPH. Full-face portrait with a trimmed size of between 2 × 1½ ins. and 2½ × 2 ins. included in passports. As the photographs are intended purely for identification their standard does not need to be high in other respects. For this reason passport photography is generally carried out at cut-price rates by firms which specialize in cheap portraiture. Two such portraits must be produced with a passport application in Great Britain; one to paste into the passport and the other for the official files.

See also: *Identity photographs.*

PASTE. Two types of paste are used in photography—mountant pastes, for sticking prints to mounts and into albums, and encaustic paste which is rubbed into the surface of a print to improve its appearance.

PATENTS. The grant of British Patents for inventions is governed by the Patents Act, 1949–57, and the Patents Rules, 1958–63. Copies of the Act and Rules and Patent Specifications may be consulted free of charge at the Patent Office in London and various major public libraries.

The following brief notes are intended as an introductory guide. Comprehensive pamphlets which are available free of charge from the Patent Office.

Obtaining a Patent. An application for a Patent has to be made on a special form (£1 fee) and must be accompanied by a description of the invention (known as a specification) together with drawings if necessary for a clear understanding of the invention. The specification may be either Provisional (no fee) or Complete (£10), but if Provisional it must be followed by a Complete Specification normally within twelve months. This time allowance is to enable the invention to be more fully developed and careful consideration to be given to the drafting of a Complete Specification. This must be a full and detailed description from which a competent workman could carry the invention into practical effect using only the document and drawings (if any) and without further directions. The Provisional Specification, on the other hand, need only disclose the basic features of the invention, although as much as is possible should be described. The filing of an application (£1) with a Provisional Specification establishes a priority date and gives the inventor an option, so to speak, on a consequent Patent, and thereby forms an interim measure of protection. A Provisional Specification does not constitute a Patent but merely forms a legal basis for the earlier date (the priority date) to be accorded to a subsequent Complete Specification. A Provisional Specification is not published, and its contents remain confidential to the Patent Office until a Complete Specification is filed, accepted and published.

No models are required nowadays. Patents are granted on payment of a sealing fee of £3 following satisfactory examination of the documents. Thus the basic cost of obtaining a Patent is £14 (£1 on application, £10 on filing a Complete Specification, and £3 sealing fee) and this covers the first four years from the date of filing the Complete Specification.

CC-0. Apertura Digital Preservation Foundation Inc. Chapapote

Thereafter annual renewal fees are payable (if it is desired to keep the Patent in force) until its final expiry after sixteen years.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The granting of a Patent does not imply that there is any commercial value in the invention, and it should be realized that few of the 30,000 inventions patented annually ever become a financial success.

Value. A Complete Specification must end with a summary of the main novel feature of the invention and any important subsidiary features. This should be in the form of clear, brief statements (known as claims).

The value of a Patent depends mainly on the wording and validity of the claims of the final Complete Specification. Specialists, known as Patent Agents, are usually employed to draft at least the Complete Specification. Obtaining a really useful Patent can be an expensive enterprise and the would-be patentee is strongly advised, before filing a Complete Specification, to consult a reputable manufacturer as to the probable value of his invention. Some manufacturers advertise their willingness to consider "gadgets" and give experienced advice as to the best course to adopt. The reputation of such advertisers should be checked before disclosing what might be a valuable idea, and the prior filing of an application for a Patent with a Provisional Specification is always a wise precaution. As a Provisional Specification must be followed by a Complete Specification within twelve months, a manufacturer should be approached well before the end of that period to leave enough time to proceed with the application.

Patent Rights Abroad. If it is desired to obtain Patent rights outside the United Kingdom application has to be made to the government of the country in which protection is desired, be it one of Her Majesty's Dominions or a foreign state. The procedure varies considerably and prospective applicants are advised to consult a registered Patent Agent. Under the terms of an international convention an application for a Patent in most countries abroad, if made within twelve months of the date of application in the United Kingdom, has the same effect as if made on the day the application was made in the United Kingdom. A list of such countries is given in the free literature available from the London Patent Office.

Applying for foreign Patents can be an expensive procedure, and an international search is to be recommended. This might reveal lack of novelty in the invention and thereby save the costs of making applications. A Patent Agent can arrange for a search to be made.

Patents in the U.S.A. The United States of America offers a particularly wide market for photographic equipment and its Patent procedure is therefore worthy of special attention.

An application for a Patent by a citizen of the United States has to be made with a formal Petition (this usually includes a Power of Attorney in favour of a registered patent attorney or agent) and Oath of inventorship, accompanied by a full description of the invention is the form of a specification (including a drawing in every instance where the nature of the case admits of illustration) and Claims (stating precisely what is to be protected). A filing fee of $30 (exclusive of attorney's fees) must be paid. On approval a further fee of $30 is payable before a Patent is granted. There are no further fees or taxes and the protection lasts for 17 years from the date of issue.

The most vital part of the application is the Claims and as these have to be filed in the first instance it is desirable to employ a patent attorney. Names of attorneys may be obtained from the nearest Patent Law Association. This will, of course, increase the cost of obtaining a Patent. It is wise to have a search made before applying for a Patent as the filing fee is not returnable if no Patent is granted.

There are several good books published giving practical advice on all aspects of inventorship. These may be consulted in public libraries or obtained from the Patent Office in Washington.

Should the cost of obtaining a Patent be a deterrent there is an alternative course available. This is to make a complete written description, in duplicate, of the objects and purpose of the invention, describing its construction and operation in detail, including whatever drawings or sketches assist in understanding it. One copy of the papers should be signed and dated by the inventor and two reliable witnesses who understand the invention. The signed copy should then be carefully preserved and the unsigned copy sent to a likely manufacturer. This procedure is even more valuable if the invention has first been put into practice and successfully operated before two witnesses who understand it. Only manufacturers of repute should be consulted as there is no legal redress until a patent (for which the above document is valid proof of inventorship) has been obtained.

R.E.

PAUL, ROBERT WILLIAM, 1869–1943. English engineer and scientific instrument maker. Pioneer of cinematography. Copied Edison's Kinetoscope in 1894. Built in 1895 a cine camera, and in 1896 the first English cine projector, the "Theatrograph". Made the first English films; later he made (with Professor Silvanus Thompson) animated films for teaching. In 1912 he abandoned cinematography and devoted himself entirely to precision instrument building. His works were taken over in 1920 by the Cambridge Instrument Company.

PEARL LAMP. Ordinary filament lamp with a bulb sprayed or frosted to diffuse the light. Not to be confused with the opal type of lamp.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PERIODICALS

The function of the periodical press is to report on new developments, to keep readers stimulated and to serve dealers and manufacturers as advertising media in their particular market.

Photographic periodicals are produced by independent publishers, photographic societies and trade associations as well as by major manufacturers and even retailers. Their revenue is derived only in part from what the readers pay for the publication whilst the other, sometimes the larger, part is contributed by advertisers or sponsors.

Types. Most periodicals are published monthly. Some, however, appear quarterly, bi-monthly and a few are weeklies. Prior to the second World War, at least two German journals were published twice weekly. The frequency of publication is, as a rule, due to commercial considerations and is of greater concern to advertisers than to readers. The actual volume of genuinely new and important information of photographic interest is limited and thus the inevitably repetitive element of the editorial contents is as a rule inversely proportionate to the length of the period that separates two consecutive issues of any periodical.

Photographic periodicals may be classified as technical, pictorial or trade journals although the three groups often overlap. Most amateur magazines gravitate towards the middle group.

Standards, methods and policies vary a great deal. Readers' interest always ranks as the first consideration in selecting and angling editorial material—but first of all must come the decision as to what sphere of readers the publication in question is to attract. It is at this critical stage that the interests of advertisers, organizations or sponsors are taken into account and where the basic compromise is reached between serving the public and paying the publication's bread and butter expenses.

Periodicals professing lofty aims and maintaining an aggressive independence have a notoriously low chance of survival. This is particularly true of those crusading, from time to time, for some artistic principle.

High level technical journals often have to be specially underpinned by the photographic industry, by learned associations or simply by the selfless enthusiasm of their editors and contributors. The higher their level the lower are the fees they can pay for contributions.

Trade and market journals are sometimes linked to associations whose interests they represent, in which case a fair proportion of their contents is bound to be devoted to business politics. Independent publications have to aim at a brighter editorial approach to compensate for some first hand news which may be monopolized by the "official organs".

The greatest variety of approach to and presentation of the subject is found among magazines for amateurs. Their basic components, however, are inevitably similar; pictorial examples, technical articles, reviews of new equipment, ideas for gadgets and notes on and by personalities and groups. The differences result from the choice of readership level, the proportion of the contents devoted to the various spheres of interest, and, last but not least, the personality of the editor.

Policies. Editors are experts and are reputed to know and preach "more and more about less and less". Editors with pronounced personal interests in some special aspect of or opinion on photography are apt to revert to the relevant points with a frequency which is bound to slant their work and tire their readers. Variety, balanced views, and an invigorating outlook, are more easily ensured by a large editorial staff than the somewhat out-moded device of perennial outside columnists and so called steady contributors.

The contemporary trends in photographic journalism generally indicate preference for more and better pictorial examples, simple and concise copy, bright and stimulating approach and free interchange of views with the reader.

Readership. The circulation of periodicals varies greatly from country to country and also, of course, with their level of contents and the business efficiency of their publishers. Top circulation claims approach a quarter of a million in the United States, well under a hundred thousand in Great Britain, under fifty thousand in Germany and much lower in France, Italy, Sweden and Switzerland.

The advertiser is less interested in absolute figures than in the relative size of specific market coverage any periodical may offer and whether this coverage is expansive, stationary, receding or seasonally fluctuating.

For the reader, what matters is not how many other people read the same magazine but whether he likes what he reads.

Obviously the reader's choice of periodical reading will be conditioned first and foremost by his own interests. If these are pictorial, he will know only too well what type of pictures and so which pictorial magazine he prefers. If his interests are technical, his own level of understanding will be as sure a guide as any, and he will soon learn to distinguish journalistic bluff hiding behind terminological fireworks from genuine information. If his hobby is centred on clubs, exhibitions and societies, he has only to look for the journals which provide most of that type of news. Specimen copies are supplied free as a rule and the choice is so wide that there is no reason for any photographer not to have the periodical he needs, likes and deserves. A.K.-K.

PERIPHERY PHOTOGRAPHY Technique of photographing all-round views of objects to obtain a flat "rolled out" picture. Such pictures may be obtained either by rotating the object in front of a camera fitted with a moving film system, or by surrounding the object by an all round optical system that records the whole circumference simultaneously.

Periphery Camera System For this method the object is set up on a rotating turntable opposite the camera. The latter has a travelling back to move the film during the exposure. The lens projects the image of the object on to the film through a narrow slit, which ensures that only that part of the object directly facing the lens axis is recorded at any instant.

The film holder and turntable are driven by motors synchronized to keep the image sharp during the exposure. The speed of the turntable and of the film holder are linked in such a way that the film travels through its full length while the turntable rotates through one revolution.

A camera of this kind can handle objects of sizes from several feet in diameter down to a fraction of an inch (for example a pencil surface). The scale of reproduction must be accurately related to the size of the object and hence to its distance in front of the camera lens. For that reason a camera set-up of this nature can only deal adequately with objects of approximately cylindrical shape where all surface features are more or less in one plane.

SET-UPS FOR PERIPHERY PHOTOGRAPHY. A, portion of cylinder or other round object imaged on the film. B, lens. C, extent of plate movement. D, travelling plate. E, slit. The distance between the object's surface—either the outside (top) or the inside (bottom)—and the lens is matched with the lens-to-plate distance and the plate movement so that the latter covers exactly the external or internal circumference of the object.

Parts of the object that project appreciably behind that plane would move at a different speed during the rotation of the turntable and therefore lead to a distortion (and often unsharpness) of the image on the film. The degree of unsharpness under these conditions depends on the slit width. At its narrowest setting this is usually around 0·003 in., which gives sharp but still distorted images of object features whose movement speed did not exactly match the film movement.

The resulting image on the film covers a full 360° view of the circumference of the object, but in a flat plane. This is frequently more suitable for the examination of surface details than any orthodox view could be.

Panoramic Mirror Systems Instruments that provide a simultaneous all-round view of the circumference of an object use a panoramic mirror surrounding the object itself. The latter goes through the centre of the mirror, which then projects an image of this circumference view through a further mirror system into an eyepiece or on to a photographic film. Compared with a periphery camera, this arrangement needs no moving film, but is limited to smaller objects. (In practice mirror systems like this exist taking objects up to a diameter of about 4 ins.) The image produced is distorted, consisting of a flat ring, the circular inner and outer boundaries of which define the limits of the field of view along the axis. Since the image itself is stationary, an additional dimension of movement can be brought in to record different sections along the length of the object with a cine camera. This technique has been used to check the production of continuous lengths of items like steel cables, machined rods, etc.

The circular image can be converted into a flat one by a reversing optical system that projects the periphery image in a curved plane surrounding the optical system. If a photographic film or paper is wound around this image plane, it can be unrolled after exposure and processing to yield a flat and rolled-out but undistorted view of the object. The light source for such photography is usually a ring light surrounding the panoramic mirror of the taking system. By linking the optical rectifying system directly with the panoramic mirror unit, a flat rolled-out image can be produced by a single exposure. L.A.M.

PERMITS TO PHOTOGRAPH. With certain exceptions people are allowed to photograph anything to which they have obtained legal access. The exceptions are subjects coming under the Official Secrets Act, certain subjects covered by copyright, anything obscene, views in the Law Courts, and the Houses of Parliament. For the latter, permission may be granted upon request but only when the House is in recess.

When a photographer wishes to take photo-

CC-0. Agamnigo Digital Preservation Foundation, Chandigarh

graphs on private property or in a private building, requesting permission is a matter of good manners. It is always as well to ask before starting to take pictures if there is any doubt. Permission should be asked to take pictures inside cathedrals, churches, historic buildings or private houses, and if possible the permit should be obtained in advance of the visit. A letter to the dean of a cathedral, the vicar of a church, or the custodian or owner of private property will usually have the desired effect.

A stamped addressed envelope should always be enclosed as a gesture of courtesy.

No one is normally given permission to take photographs in a church whilst a service is being conducted. The one exception is at a wedding ceremony, but in that case the vicar must always be consulted first.

In some parks and public places it is necessary to have permission to erect a tripod. This is because a tripod constitutes an obstruction and there are often bye-laws controlling or prohibiting their use. Anyone who particularly wants to use a tripod in such places should apply for permission to the Park Superintendent.

No one needs permission to take photographs of other people provided the photographs truthfully represent the subject and are not libellous. Even so it is only courteous to ask permission to photograph a stranger, and usually an offer to supply a print is all that is required to procure a willing sitter.

Photographs may not be taken in the cinema, at the theatre or the circus without permission. The cinema and theatre have the question of copyright to consider and although photography is occasionally permitted at the theatre the photographer must make sure of it first. The circus is a different matter. Permission is usually given readily, and one circus even has a competition for the best photographs taken during a performance. The only provisions are that camera users must not stand up, or interfere with anyone else's enjoyment, nor must they use flash except at a special photo-call.

Photography is also prohibited in most military and atomic energy installations.

Regulations abroad generally follow the same pattern as in Britain, though in a number of countries restrictions are more severe and may include strategic factories, bridges, port installations, etc. G.W.P.

PERSPECTIVE

Perspective is a graphic device which artists use to reproduce the appearance of scenes and solid objects on a flat surface—i.e., for representing a three-dimensional subject in two dimensions. There is more than one method of perspective representation, but the method generally employed by draughtsmen and photographers is the simplest. This supposes that the observer is looking, with one eye, through a window pane at the scene, from a fixed viewpoint opposite the centre of the pane. Seen in this way, the outlines of the various objects in the scene can be imagined as being drawn on the glass, and if the whole scene were actually filled in with a pencil or brush, the result would be a picture in two dimensional perspective. This imaginary window will be useful in explanations that follow; it must be remembered, however, that this is only an artificial device for convenient description.

PRINCIPLES

There are three things that the photographer needs to know about perspective: the basic principles, perspective as it is interpreted by the camera and the subjective aspect—i.e., the mental impressions produced by the perspective picture.

The picture that would be produced by drawing over the outlines of the scene framed in an imaginary window pane has only two dimensions; it shows the relative positions of points in the field of view embraced by the frame, but not their distance from the observer. Distance in the perspective picture is conveyed by size. A football would appear as a circular disc, which would grow proportionately smaller as the football went farther and farther away. One football twice as far away from the observer as another would be represented by a disc of half the diameter. Similarly the apparent separation between parallel lines—e.g., the edges of a road or the rails of a railway—running away from the observer gets less and less as they recede; at one point twice as far from the observer as another, the separation is half as much; three times farther away, it is one-third as much, and so on. On the other hand, the separation between parallel lines running across the scene parallel to the window pane is to all intents and purposes constant because all points are at the same distance from the plane of the window.

Viewpoint and Picture Plane. An object in the scene subtends the same angle at the viewpoint as its perspective image on the picture plane—i.e., on the window pane. Both the object and its image may therefore be regarded as the bases of similar triangles whose common apex is the eye of the observer at the fixed viewpoint. So in a perspective view, the size of the object is to the size of the image as the distance of the object from the viewpoint is to the distance of the image from the viewpoint.

In other words, when the observer traces on the window pane the outline of an object seen through it, the closer his eye is to the window,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SCALE AND PERSPECTIVE. Moving the picture plane farther away from the eye of the observer increases the scale of the image but does not alter its perspective.

the smaller the outline image will be in relation to the pane, and the farther away, the larger. (If the window is so far away from the viewpoint that it actually touches the object, then the image on the screen will be the same size as the object.)

But as the eye of the observer comes closer to the window, and the relative sizes of things get smaller, more things are included in the area enclosed by the frame. And as the observer backs away from the window, the relative size of things seen through it increases and fewer things are included in the area enclosed by the frame.

With a short distance between the eye and the pane, the eye can survey a wide angle of the scene and see a large number of objects which form relatively small images in the picture plane. With a long distance between the eye and the pane, the eye is forced to observe only a few objects within a narrow angle of view. But since the frame is the same size in each case, the few objects that fill it in the second case will appear correspondingly larger in scale than in the wide-angle view.

In practice the closest distance at which the average human eye likes to look at things is 8 to 10 inches. So normal scenes are drawn (or photographed) as though traced on a picture plane about ten inches away from the eye.

Size and Viewpoint. In the perspective picture it is the relative size of objects in the scene that fixes their position. Of two objects of the same actual size the one that traces the smaller image will be the farthest away. But their relative sizes—i.e., how much bigger one is than the other—will depend on how far they are away from the observer.

If the observer is looking along a line of evenly spaced telegraph poles with his back against the first, then the third pole, which is twice as far away as the second, will be half the height. The fourth pole will be only $1\frac{1}{2}$ times as far away as the third so it will be only 2/3 the height. The 25th pole will be 23/24 of the height of the 24th, and so on.

The same relationship will apply to equidistant points on an object—i.e., the farther they are from the viewpoint the closer they approach each other. And their separation is greater near the viewpoint—e.g., from 1/2 to 2/3, etc.—than it is farther away—e.g., from 24/25 to 25/26, etc. So the first telegraph pole in the row appears very much taller than the second and the 24th appears very little larger than the 25th, yet all the poles are the same size and are equally spaced.

The change in relative size depends solely on the distance from the viewpoint; it does not matter how large or how small an area of the scene is included. If the frame of the picture

DISTANCE AND PERSPECTIVE. The relative size of near and distant objects—i.e., their perspective—depends upon their distance from the viewpoint. When the viewpoint is close, the relative size of near objects is exaggerated. A: Seen from the near viewpoint the first pole appears twice as tall as the second. B: Seen from a farther viewpoint, twice as far away, it appears only $1\frac{1}{2}$ times as tall. Also, succeeding poles diminish less in size, and the distance between them in the image decreases only slowly.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SIZE OF FRAME AND SCALE. Left: *Pictures must be viewed at such a distance that they lie within the angle of view of the eye, i.e., 50°. I they lie outside (broken line) they call for an abnormal amount of eye movement.* Centre: *To lie inside the comfortable viewing angle the picture must be looked at from a distance not less than its diagonal.* Right: *A small picture from a near viewpoint looks the same when enlarged to twice the size at twice the distance.*

cuts off the first twenty-three poles, the second pole in the picture—i.e., No. 25—will still be only 23/24ths the height of the pole in front, and not half the height.

This change in the relative size of objects receding from the viewpoint is the thing that fixes the perspective of the picture. So the perspective is a function of viewpoint only, and is not influenced by any other factor.

Size of Frame. With the eye at any given distance from the picture plane, the size of the frame does not affect the real size of the image. A small frame will include only a correspondingly small part of the scene while a larger frame would include more, but the size of the images traced on the picture plane would be the same in each case.

There is no limit to the amount of the scene that can be included in the picture; it is only necessary to go on increasing the size of the frame. But in practice the human eye can only take in objects included in an angle of about 50°. So the normal practice is to limit the size of the finished picture to dimensions that fall within the angle of 50° covered by the eye from its most convenient viewing distance. This means that the diagonal of the picture should be about equal to the viewing distance—e.g., a picture looked at from 10 ins. away should not normally exceed 6 × 8 ins.

Scale. The size of the image traced by an object on the picture plane in relation to the size of the frame increases as the picture plane is moved farther away from the viewpoint and towards the scene. If the separation of the viewpoint from the picture plane is doubled, the size of objects included in the picture will be doubled also. But the same result can be produced by enlarging the original picture to twice the size. In both cases the perspective of the picture remains unaltered and there is nothing in the appearance of the image of a particular object to show whether its scale has been enlarged (or reduced) by altering the viewpoint-picture plane separation or by keeping the separation constant, tracing out the scene, and then enlarging the result. In each case the scale of the objects and their perspective will be the same.

Looking from its fixed viewpoint, there is nothing to indicate to the eye (apart from the purely physical difficulty of focusing very close objects) whether it is looking at a miniature perspective picture 1 in. away, or one ten times as high and wide but 10 ins. away, or one 100 times bigger but 100 ins. away. Neither the scale nor the perspective nor the area enclosed by the frame are changed by making the same proportionate change in both viewing distance and frame dimensions. So the artist can please himself whether he paints a miniature portrait to be looked at one foot away or a larger picture to be looked at from a proportionately greater distance.

Horizon. If the picture plane is vertical and the viewpoint is opposite the centre of the frame (the basic assumption in normal plane perspective) then the horizontal line joining the viewpoint to the centre of the frame if produced will meet the horizon, and the line of the horizon will bisect the resulting picture. If the horizon is above or below the centre of a picture this is either the result of deliberately omitting part of the picture, above or below the horizon, or of a departure from the conditions of normal plane perspective.

The position of objects in the picture in relation to the horizon is an important factor that indicates their proportions. Assuming a normal viewpoint of about 5 feet from the ground, then all points at that height lying directly between the viewpoint and the horizon will be on the level of the horizon. Wherever the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

VANISHING POINTS. Parallel lines receding directly from the observer appear to meet at a point (called the vanishing point) on the horizon in the centre of the picture plane. Right: When the parallel lines are at an angle to the horizon, the vanishing point lies off the centre or even outside the picture plane. The horizon itself corresponds to the height of the observer above the level of the lowest part of the subject. It can be raised or lowered at will.

line of the horizon intersects objects in the picture, the point of intersection will be 5 feet above the ground. So the height at which the horizon intersects any objects in the picture is also an indication of the height of the viewpoint above normal ground level.

Vanishing Point. In a perspective reproduction of a scene, all parallel lines which appear to converge will continue to approach each other in direct proportion to their distance from the observer, until finally they meet at a point on the horizon. This point is known as a vanishing point; there is one such point for all parallel lines lying in the same plane.

For all parallel lines normal to the picture plane the vanishing point lies on the horizon at the centre of the picture. As the parallels incline to one side or the other of the normal, the vanishing point moves right or left until finally it passes outside the frame. When this happens, the vanishing point will still lie on the horizon, but the horizon will have to be extended outside the frame. The limit is reached when the lines lie parallel to the picture plane and the vanishing point lies at an infinite distance along the extended line of the horizon.

Oblique Perspective. Everything that has been said above assumes that the picture plane is vertical, but the same principles can be applied to show what happens when the picture plane is tilted.

From the point of view of an observer drawing over the outlines of the scene looked at through a window pane, it makes no difference whether the picture plane is vertical or tilted. The picture that he traces on a sloping pane will still fit over the scene as he sees it so long as he looks at it from the same viewpoint and holds the frame at the same angle.

But if the picture traced under these condi-

OBLIQUE PERSPECTIVE. This occurs when the picture plane is at an angle to the subject plane. Where the picture plane is brought nearer to the subject, the scale increases; where it is moved farther away, the scale decreases. AB and centre: Subject as shown on normal picture plane. CD and right: Subject as shown on oblique picture plane.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tions is looked at in the normal way—i.e., held up straight—the relative proportions of the various objects will be different from those given in a normal plane perspective.

Suppose the picture had been traced with the top of the frame tilted forward towards the scene. Then the picture plane would be closer to objects in the upper half of the scene than in the lower half, and the top would be farther away from the viewpoint. This means that the objects in the upper half of the scene would be reproduced on a larger scale than those in the lower half, and vertical parallel lines would therefore appear wider apart at the top than at the bottom of the picture. They would only appear parallel if the picture were sloped away from the observer at the original angle at which it was tilted.

In addition to increasing the scale of all objects in the upper half of the picture, the forward tilt of the picture plane would also increase the perspective of the objects in proportion to their increased nearness. (The difference in size between perspective images of objects increases progressively as they approach the picture plane as illustrated by the telegraph pole example above.)

Similarly inclining the picture plane to make the top slope away from the scene would result in a picture in which vertical parallel lines would be wider apart at the bottom than the top, and the perspective of objects in the lower part of the picture would be increased.

Parallel lines running across the picture from side to side would remain parallel on the tilted picture plane but their linear separation on the plane would increase with increasing tilt —in other words the scene would be stretched out from top to bottom, a smaller amount of the scene being drawn out to fill the full height of the frame. A similar thing occurs when a circle of light shines on to an oblique surface: the circle becomes elongated and requires a larger area to accommodate its full circumference.

So tilting the picture plane has three effects on the appearance of the perspective picture:

(1) It enlarges the scale of objects progressively as they are brought closer by the tilt.

(2) It increases the perspective of objects brought closer by the tilt.

(3) It elongates the subject in the direction of the tilt.

Panoramic Perspective. It has already been said that there is no limit to the amount of the scene that can be included in the picture by making the frame larger—or by bringing the viewpoint closer to the picture plane. This is all very well in theory, but in practice there are objections because the human eye is unable to embrace an angle greater than about 50° and pictures covering such a wide field are apt to appear distorted when looked at in the normal way.

The apparent distortion results from the fact that the picture plane is only really normal—i.e., square on—to the line of sight at the very centre. The picture plane becomes increasingly oblique to the line of sight away from the centre, and the bigger the frame, the more oblique will be the angle of the picture plane at the edge of the picture.

PANORAMIC PERSPECTIVE. AA: *At the centre, the picture plane lies at right angles to the line of sight and objects are represented in normal perspective. Towards the edges of the picture, the plane becomes more and more oblique and produces more and more of the characteristic distortion. When the picture plane is wide in proportion to its distance from the eye of the observer—i.e., in a panoramic view—the distortion is proportionately great.* BB: *To present a live impression of the scene it is necessary to use a curved picture plane with the eye situated at its centre curvature.*

It was shown above that when the picture plane is at an oblique angle the result is to enlarge, elongate and increase the perspective of the objects traced out on it. All these effects occur towards the edges of the field covered by the picture plane and are more pronounced as the edges get farther away from the centre.

Curved Panoramic Perspective. There is another way of arriving at a perspective view of an abnormally large scene which has none of the above objections. This is to trace out the scene on a curved picture plane with the viewpoint at its centre of curvature. In this case the picture plane is always normal to the line of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

sight, so there is no distortion of the picture towards the ends of the picture. There is in fact no "ends" to the picture; it can extend for the whole 360° of the horizon.

The viewpoint in this type of panorama must always be at the centre of curvature and the picture plane must be curved; if the picture is viewed normally it appears false.

The image formed at the focal plane in the camera corresponds to the image that would be traced by an observer with his eye in place of the lens on a picture plane at the focal distance of the lens. (Except that the camera image is inverted because the light rays from the subject cross over in passing through the lens.)

CAMERA PERSPECTIVE. The camera image formed by a 10 ins. lens corresponds to the picture traced out by an observer on a window pane in front of him, 10 ins. from his eye. AB picture plane. A_1B_1, camera image.

PERSPECTIVE IN THE CAMERA

The image formed on an 8 × 10 ins. focusing screen by a 10 ins. lens corresponds exactly to the picture that an observer would see if he looked at the same scene through an 8 × 10 ins. window 10 ins. away from his eye. If a miniature camera with a 2 ins. lens were pointed at the same scene, the image formed on the film would compare in every respect with the picture on the focusing screen of the larger camera except that it would be 2/10 the size—i.e., 1/5. It would correspond to the image formed by moving the picture plane from 10 ins. to 2 ins. away from the eye and reducing the height and width of the frame in proportion.

If the picture produced by the smaller camera were enlarged five diameters, it would be identical with the 8 × 10 ins. picture. Similarly a camera with a 5 ins. lens would give a picture which would be identical with the 8 × 10 in. pictures after 2× enlargement.

Normal Lenses. The general aim in taking a photograph is to recreate the impression of the original scene. While the original scene would be related to a picture plane of any size at any distance from the observer, people mostly hold things about 10 ins. away for comfortable viewing and their eyes have an angle of view of about 50°. So a photograph should reproduce the effect of looking at the original scene through a frame with a diagonal of 10 ins. and held 10 ins. away from the eye. This gives an angle of view of approximately 50°.

These conditions can be met directly by a camera with a 10 ins. lens working on a plate with a diagonal of about 10 ins.—e.g., a whole plate (6½ × 8½ ins.) camera. A contact print from such a camera held 10 ins. away from the eye would reproduce the effect of looking at the original scene through a 6½ × 8½ ins. window. The same conditions can be met by subsequently enlarging the negative from a 2 ins. lens five times, a 3 ins. lens 3·3 times and so on.

In each case, to fulfil the required viewing conditions, the focal length of the lens must be approximately equal to the diagonal of the plate or film covered. Such a lens is regarded as the normal lens for that particular negative format. The normal lens for a 35 mm. miniature camera—negative 1 × 1½ ins. (24 × 36 mm.), diagonal approx. 1·75 ins. (43 mm.)—is 1¾–2 ins. (4·5–5 cm.); for 2¼ ins. (6 cm.) square cameras—diagonal approx. 3½ ins. (80 mm.)—is 3–3⅜ ins. (7·5–8·5 cm.) and so on.

Any camera with a normal lens of focal length = f will give a picture in natural perspective for viewing at 10 ins. if the negative is enlarged $10/f$ times.

Generally, if the normal lens of the camera is replaced by one of n times its focal length, then the image size will be multiplied n times on the new negative while an identical picture can also be produced by enlarging the original negative n times. If the whole of the "normal" negative is enlarged, the dimensions of the picture will, in addition, be n times the dimensions of the long-focus picture.

Long-focus Lenses. If the picture plane is moved farther away from the observer's eye, it includes less and less of the scene but the perspective remains unchanged; 20 ins. away from the eye, the frame will include only half the picture width that it included at 10 ins. But all the objects in the field included will be twice as big in relation to the frame as they were before.

The same effect is produced by doubling the focal length of the camera lens. A long-focus 20 ins. lens will cover only half the field of the normal 10 ins. lens, so everything will be reproduced at twice the previous size. But the perspective of the picture will not be altered. So that the same picture would result from enlarging the corresponding part of the negative taken by the 10 ins. lens (and covering the larger view) to twice the size.

This holds good equally for all other sizes of camera and standard lenses when the focal length of the lens is doubled without altering the viewpoint.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FOCAL LENGTH AND PERSPECTIVE. The focal length of the lens alters the size, but not the perspective of the image, provided the subject-camera distance remains the same all the time. Top: *Subject taken with normal lens.* Centre: *Taken with wide-angle lens from same viewpoint.* Bottom: *Taken with long-focus lens from same viewpoint.* Right: *Subject taken with long-focus lens from more distant viewpoint gives normal sized image with flatter perspective.*

Wide-Angle Lenses. If the normal picture plane is brought closer to the eye—e.g., to 5 instead of 10 ins.—the resulting picture will include twice as much of the scene. All the objects in the scene will be half the original size in relation to the window, but their perspective will remain the same, except that panoramic perspective distortion, as mentioned earlier, will increase as the angle of view widens.

This corresponds to what happens when a lens with a focal length shorter than normal—i.e., a wide-angle lens—is used in the camera. As for the long focus lens, if the normal lens is replaced by one of $1/n$th the focal length, then all objects in the field will be reduced to $1/n$th the normal image size. An identical image of the objects common to the normal and wide-angle negatives can be produced by reducing the scale of the normal image by $1/n$th, but the dimensions of the resulting picture would only be $1/n$th the dimensions of the wide angle picture.

CONTROLLING PERSPECTIVE

It will be clear from what has been said above that there is no direct connexion between the perspective of the picture and the focal length of the lens. From the same viewpoint, all lenses give a picture with the same perspective. If one lens gives a smaller image than another, the situation can be restored by enlarging. And no matter what the size of the camera or the focal length of the lens, the resulting negative, or part of it, can always be enlarged to produce a print which, when viewed from the normal distance of 10 ins., will present the original scene in its natural perspective. When using long focal length lenses and small negative material, such correct prints would prove impracticably small, however.

The main object in using a long focus (or telephoto) lens is to get a bigger picture of the subject on the negative when it is not possible to get it by going closer to the subject.

The main object in using a short focus (or wide angle) lens is to take in more of the subject when it is not possible to include everything by moving farther away.

Neither of these functions is primarily concerned with the effect of the change on the perspective of the picture.

But there are occasions when the sole object of using these lenses is to achieve a particular effect of perspective and not because it is impossible to get close enough to include less, or far enough away to include more of the scene with a normal angle lens.

Normal Lens. Within limits, there is no need to use a special lens to control the perspective of the picture. Perspective is controlled by viewpoint and nothing else.

By coming close to the subject, the picture can be given the violent type of perspective in which objects get smaller very rapidly as they go farther away. The disadvantage of this method is that as the camera comes closer, the field covered by the lens shrinks in proportion, so less of the scene appears in the picture.

By moving farther away from the subject, the picture can be given the type of perspective in which objects get smaller very slowly as they recede. The disadvantage of this method is that, as the camera goes farther away, the size of the image gets smaller and the picture includes more and more of the scene for which the photographer has no use. It is possible to get over the difficulty by masking off the unwanted part of the scene and enlarging the remaining important part to the required size. Up to a point this is an excellent, plan, but where only a small portion of the negative has to be greatly enlarged, the loss of quality is a serious drawback.

There are thus definite limits to the extent to which it is possible, with a normal lens, to choose a viewpoint which will give the desired effect of perspective. The long and short focus lenses extend these limits.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Long-focus Lens. The long-focus lens gives the photographer the large-scale image that is associated with a close-up viewpoint, but with the gentle perspective associated with a distant viewpoint.

The classic example of this occurs in portraiture where the perspective resulting from a close viewpoint is apt to be neither pleasing nor characteristic. There are two separate reasons for this.

(1) The closer the sitter is placed to the camera, the greater the disproportion between the distances of near and far features becomes. When the head of an average sitter is pointed towards the camera, the tip of his nose is about 6 ins. nearer the lens than his ears. So that if the camera is 4½ feet away from the sitter's nose, that feature is 1/10 nearer the camera than the ears and will be reproduced on a scale 1/10 larger than the ears. A more distant viewpoint—up to 15 feet—restores the proportions to acceptable standards while the use of a lens, with a focal length of two or three times normal enlarges the image to the same size as would be produced by a close-up viewpoint with a normal lens.

(2) As the lens is brought closer to the head of the sitter it looks at it from a wider and wider angle, and sees less and less of the sides of the face. So the features in the centre of the face—e.g., nose, mouth, eyes—appear larger in proportion to the whole area seen by the camera. A normal mouth is about one half as wide as the face, but from a close viewpoint it may appear as much as two-thirds the width, and the ears may not even show at all. Such a portrait would give a false impression of the actual appearance of the face.

Here again, a more distance viewpoint restores the natural proportion, and the long-focus lens enlarges the image as needed.

Wherever it is necessary to prevent objects nearer the camera from over-shadowing those farther away, the standard technique is, first, to choose a viewpoint far enough away to show the near and far objects in the desired perspective proportions, and then to magnify the important area of the scene until it fills the whole picture area. This technique applies equally to portraiture, still life, landscape and architectural photography, and it should not be confused with the use of a long-focus lens simply to produce a bigger image than would be given by a normal lens—e.g., in sports photography and astronomy.

Wide-angle Lens. A near viewpoint gives a perspective in which the size of near objects is increased in relation to those farther away. Where this effect is undesirable, the answer is to adopt a more distant viewpoint, but on occasion it offers a useful means of lending importance to the subject and of playing down other objects in the picture area. A lens of normal focal length includes less and less of the subject as it is brought closer, and so, while the perspective of the close viewpoint may be satisfactory, the amount of the scene included may be too small.

A wide-angle lens—i.e., one which has a shorter-than-normal focal length—enables the camera to be brought close to get the required perspective, but it also covers a larger-than-normal field, so that the whole of the subject included with its angle of up to 100° is the same as that covered by a normal lens with its angle of about 50° working from a correspondingly greater distance. The field is the same, but the perspective is different.

This technique is used for making a particular object or part of the subject—e.g., a building—appear very much larger than the background and objects immediately behind it. This use of a wide-angle lens to control perspective is quite distinct from its use from a near viewpoint to cover a larger area of the field than could be photographed with a normal lens—e.g., in making a record of the interior of a building where the camera distance is limited.

Camera Movements. Finally, perspective can be controlled in the camera by the use of the various camera movements. The principle is the same for all the movements of the back of the camera—i.e., vertical and lateral swings—and for movements of the back in relation to the front—i.e., rise and cross front movements. (It does not apply to front swings used alone because these simply swing the focal plane of the lens to increase its effective depth of field to cover an oblique subject.)

Every camera movement of this type used to control perspective does it by altering the angle between the subject plane and the plane of the sensitized material—i.e., of the back of the camera. And the principle employed in all cases is that: all parallel lines in the scene that are also parallel with the plane of the back of the camera reproduce as parallel lines; all parallel lines in the scene that run at an angle to the back of the camera converge to a vanishing point on the horizon (either in the picture or outside it on the extended line of the horizon); and the more the parallel lines in the scene slope away from the camera, the closer the vanishing point lies to the optical centre of the picture. The optical centre is the point on the horizon immediately opposite the camera—i.e., on a straight line from the camera, normal to the plane of the sensitized material.

Correcting Horizontals. For example, if the camera is looking on a corner of a building, the sides of the building will each be at an angle to the back of the camera. So the side walls will each appear to converge to a vanishing point on the horizon. Swinging the back of the camera to bring it more nearly parallel to one of the sides will reduce the perspective of that side and in-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

EFFECT OF LATERAL SWING. Top: *The camera back is in its normal position, i.e., at right angles to the lens axis, and the resulting image corresponds to what the eye would see from the same viewpoint.* Bottom: *The back of the camera has been swung to bring it more nearly parallel to the left side of the building. This has the effect of reducing the convergence of parallel horizontal lines on that side. At the same time the convergence of the horizontal parallels on the side at right angles increases. The perspective is now abnormal but for some purposes the effect may in fact be more pleasing or even necessary.*

crease the perspective of the other. On the one side, the parallels will open out and the vanishing point will move farther away from the optical centre of the picture while on the other side they will converge at a steeper angle and the vanishing point will move closer to the optical centre. So the perspective of one side is changed at the expense of the other.

This method of perspective control is applied chiefly in architectural and industrial photography where two aspects of the same subject are to be shown in a single picture by taking a three-quarter view. It may be produced by simply swinging the back of the camera, but it can also result from the use of the cross front—i.e., the lens is moved to the side and the whole camera turned until the back is at the required angle to the subject.

The principle is also applied—though less often—to figure studies to give more pleasing proportions.

Correcting Verticals. The same principles apply to the correction of the perspective of vertical lines. In this case, when the parallel lines make an angle with the back of the camera—e.g., when the camera is pointed up at a tall building—the lines converge to a vanishing point on the vertical line through the optical centre. As the back of the camera is brought more nearly vertical by the use of forward swing of the back, the vanishing point moves farther and farther away and the verticals become more nearly parallel. When the back itself is vertical then the vanishing point will be infinitely far away and all vertical lines in the camera image will be parallel to the upright sides.

The same procedure applies equally to the less usual case in which the camera is pointed down as when taking a photograph of one tall building from the top of another. Here the verticals in the subject will converge to a vanishing point below the picture and will become parallel when the camera back is swung backwards to bring it vertical. In both the above cases overall sharpness is regained by swinging the lens-panel into a position parallel with the film plane.

When either vertical or horizontal perspective is altered in this way, the movement that restores the parallels also elongates the subject in the same direction.

PERSPECTIVE ANOMALIES

A perspective picture is essentially a picture seen or photographed from one particular viewpoint. The picture that the observer traces on the window pane will exactly correspond to the scene in front of the frame only so long as he keeps his eye in the same position. If he looks at his tracing from nearer or farther away or from one side or the other, the tracing will no longer correspond to what he sees through the glass.

In the same way, the picture drawn by the camera is only correct when seen from the viewpoint of the lens, or when an enlarged reproduction is seen from a proportionately distant viewpoint.

If a negative is taken with a normal lens of f ins., then a contact print to appear in natural perspective must be viewed with the eye f ins. away. If it is enlarged n times, then the enlargement must be looked at from $f \times n$ ins. away.

Thus, a contact print from a normal negative taken with a 10 ins. lens must be looked at from a viewpoint 10 ins. away, opposite the centre of the print. A contact print from a negative made with a 2 ins. lens would have to be looked at from 2 ins. away. As the unaided eye could not focus an image as close as this, the negative must be enlarged—e.g., 5 diameters—and the enlargement looked at from $2 \times 5 = 10$ ins. away.

An exhibition print, made from the same negative, enlarged twenty times would have to

CC-0. Agamnigam Digital Preservation Foundation Chennai

be looked at from a distance of 2 × 20 = 40 ins. A quarter of the negative enlarged on the same scale would still have to be looked at from the same distance to appear in natural perspective.

If these conditions are met, then it does not matter from what angle or viewpoint the original negative was made, nor whether it was made with a telephoto, normal, or wide-angle lens. The picture will look right. There will be no distortion of the perspective.

But these ideal conditions rarely hold in practice; they are more often than not violated either in ignorance or deliberately, and in either case the perspective of the picture will look unnatural. The eye will tolerate a large amount of some types of perspective distortion but even small amounts of other types will offend it. Two principal classes of perspective distortion occur in photography; due to incorrect viewing distance and due to incorrect viewing angle.

Incorrect Viewing Distance. In some cases the observer does not know the correct viewing distance for the picture he is looking at, and may even be misled into choosing the wrong one. If a print is put into his hand, he will automatically hold it 10 or 12 ins. away. He might then be looking at a contact print from a negative made with a 10 ins. lens (in which case he will be right) or a 15× enlargement from a negative made with a 2 ins. lens (which he ought to look at from 15 × 2 = 30 ins.) or a contact print from a negative made with a 6 ins. wide-angle lens (which he should hold 6 ins. away). All the prints could be the same size, so that there would be nothing to indicate why only one of them looked natural.

But often the choice of the wrong viewpoint is deliberate. The commonest example of this is in pictures taken with a telephoto lens with the object of showing a large image of a distant subject—e.g., of a batsman at the wicket. To appear in natural perspective, such a picture made with a 40 ins. telephoto lens should be viewed at 40 ins. At that distance, the fact that the bowler and batsman appeared about the same size would appear reasonable. But the whole idea of the telephoto lens is to give a magnified image at the normal viewing distance, so the picture is held at 10 ins. This gives the appearance of players, not four times larger than life (since that would be incredible) but four times closer. And at that close distance the observer still expects to see a noticeable difference in the sizes of the near and far batsmen. Since they nevertheless persist in looking about the same size, the unconscious conclusion of the observer is that they are much closer together than they should be, and that the length of the pitch has shrunk from 22 yards to about 5. The same effect is noticeable in telephotographs of rowing eights in which stroke appears to be sitting on bow's feet with the rest of the crew sandwiched tightly between.

Again, a picture taken with a wide-angle lens would give natural perspective if looked at from the viewpoint of the lens. If a 8 × 10 ins. contact print from a negative made with a 6 ins. wide-angle lens were looked at from 6 ins. away it would look perfectly natural, but at 10 ins. the ground appears to be sloping steeply and the scene has an opened-out look that is highly unnatural. Here, however, the choice of the lens is dictated solely by the problem of getting the widest possible field of view from an inescapably close camera position, and false perspective is the price that has to be paid.

The false appearance cannot be removed simply by enlarging until the correct viewing distance increases to 10 ins., because then the eye 10 ins. away is trying to take in a picture that extends beyond the normal 50°

VIEWING DISTANCE. Top centre: *Normal angle lens from distant viewpoint. Subject too small on viewing from normal viewing distance.* Top left: *Normal lens from closer viewpoint. Perspective still natural when viewed at normal distance.* Bottom centre: *Telephoto lens from distant viewpoint. Subject appears magnified by perspective false when viewed normally.* Top right: *Telephoto picture observed at greater distance acquires natural perspective but observer loses benefit of magnification.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

VIEWING ANGLE. For natural appearance the picture should be looked at on a level corresponding to the relative height of the camera lens at the time of exposure. If it is seen from a lower level—e.g., if it is hanging high up on the wall—it will appear in false perspective. Tilting the picture forward counteracts this. TT¹: When part of the picture is trimmed away for effect, the viewpoint does not change. It does not move to a point opposite the geometric centre of the print. The picture should therefore be viewed from its original viewpoint, even if this is opposite a portion outside the print area.

field of vision. No matter how much the wide-angle picture is enlarged, the observer will tend to back away from it until it subtends an angle of about 50° at his eye, and under those conditions the perspective will look wrong.

Incorrect Viewing Angle. Even when the eye looks at a print from the correct distance, the perspective will still look wrong unless it also looks from the correct angle—i.e., from a point corresponding to the position of the lens at the time of exposure. Generally, this is a point directly opposite the centre of the horizon on the negative. This condition again is often violated with the result that the observer feels that there is something wrong, without always realising that he is looking from the wrong angle.

Anyone looking at an enlargement from the right or left half of a negative will automatically hold it straight in front of him with his eyes opposite the centre of the print. In fact, to get the correct perspective, he ought to look at the print through one eye from a point opposite the edge along which the cut was made—i.e., opposite the centre of the original complete picture.

Similarly, when the lower or upper part of a print is trimmed away, the eyes of the observer should still look at it from a point opposite the horizon, whether the trim has left it at the top or bottom of the resulting picture.

The fact that people usually look at a photograph with both eyes means that the resulting effect of perspective is at best only a compromise. However, the difference in the angles from which each eye sees the picture gets less as the viewing distance increases; this is one of the reasons why a big enlargement is so much more pleasing to look at than a small print.

Marginal Distortion. A further cause of apparently incorrect perspective in photographs arises because the photographic recording surface is flat whereas the retina of the eye is curved.

The perspective images of objects at the edge of a picture, particularly of a wide-angle photograph, are drawn out because the picture plane is flat and so becomes increasingly oblique away from the centre of the field. But the image projected on the retina of the eye by objects in the field of vision falls on a spherical surface, with all points the same distance from the eye, so that the perspective is no different at the edges from what it is at the centre.

To a man standing in front of a row of identical posts stretching away to either side, the apparent diameter of the posts gets gradually smaller as they get farther away. But to a camera from the same position, the posts will actually get wider and wider away from the centre because each successive post records

MARGINAL DISTORTION. The images of solid objects are progressively distorted towards the margins of the plate because the off-centre rays meet the plate at an increasingly oblique angle. Distances along radial lines increase here.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

its image at a point farther from the lens and on an increasingly oblique surface. The result of this disparity between the visual and photographic perspective is that the eye rejects as false the drawn-out perspective of objects towards the edges of wide-angle photographs.

This is really panoramic perspective distortion in another guise. The significant point is that it affects only solid objects (which are seen from a different direction at the edge of the field than at the centre). If the subject is effectively in a flat plane, the oblique view of marginal areas from the lens position foreshortens apparent dimensions in that plane; this foreshortening exactly compensates for the elongation produced in the image plane.

This marginal distortion is a function of the lens angle, and has nothing whatever to do with lens construction or correction. Nor must it be confused with image distortion (such as pin-cushion or barrel distortion) introduced by the lens construction itself, though pin-cushion distortion may appear similar.

The marginal distortion due to purely perspective effects can become disturbing in wide-angle shots taken with a lens covering an image angle over about 75° on the picture format. It appears particularly pronounced where objects of obvious depth are arranged near the edges of the picture—for example heads in portrait groups, tables or other furniture of large surface expanse in interiors, etc. The greater the depth of the object relative to the width of the subject field, the more obvious the distortion effect. Such objects are therefore best kept away from the edges of the picture.

The same marginal distortion is liable to appear when vertical or horizontal sliding movements (rising or cross-front) are employed on a technical camera. In this case the image on the film in effect represents in part the marginal area of a much larger picture format corresponding to a wide-angle view. Such distortion can however be minimized, under suitable conditions, by tilting or swinging the camera back.

Converging Verticals. The most familiar example of apparently false perspective in photographs is the inward slope of vertical lines—e.g., the sides of buildings—when the camera is pointed up. Theoretically, if the eye takes up a position corresponding to the lens, the sloping verticals would be acceptable because the perspective would in fact be true to life. In practice, however, for a number of reasons, the eye will not accept the fact that receding vertical parallels converge although it is quite prepared to accept the effect in the horizontal plane. One reason is that when the eye looks up at a tall building, there is nothing to indicate directly that the verticals of it converge.

But when the image appears printed on a rectangular piece of paper, the eye can no longer ignore the inward slope. Again, the eye

CONVERGING VERTICALS. A: *A picture with converging verticals looks natural if viewed from a point corresponding to the position of the camera.* B: *It only appears unnatural when the eye is opposite the centre of the frame.*

takes in a vertical building by scanning it from bottom to top, and does not consciously compare the width of the bottom with that of the top because it does not see them at the same time (except when they are so far away that the convergence is negligible anyway). But on the reduced scale of even a large photograph, the eye can take in the top and bottom at the same time and cannot escape the fact that they are unequal in width.

The result is that to satisfy the psychological dislike of vertical convergence, the photographer has to "correct" the natural perspective by swinging the back of the camera. In so doing he actually falsifies the real facts but the important thing is that the parallel verticals look right and the photograph becomes acceptable.

With a given camera tilt the convergence of verticals appears much more pronounced with a wide-angle lens than a long focus one. This difference is also largely psychological, since the perspective of the view taken in by the long-focus lens (assuming the same camera viewpoint) is identical with the perspective of the corresponding centre section of the wide-angle view. In the latter however the very much greater convergence of lines near the edge of the picture intensifies the general impression of "falling over backwards" of the building. In the long focus view, taking in a smaller subject field, the maximum angle between the converging lines at each edge of the picture is smaller and the total effect therefore less extreme.

Compensation. From what has been said above it will appear that most photographs are looked at from wrong viewpoints, distances or angles, and with two eyes instead of one; so that in theory, few people should be able to look at a photograph without finding the perspective unnatural. In practice, however, there is always a certain amount of unconscious compensation.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

From long experience the eye becomes educated to accept a wide measure of disparity between the real and the reproduction and, fortunately for most photographers, there is rarely any need to worry about getting exact perspective.

At the same time, when dealing with straightforward subjects, the more the photographic conditions comply with the requirements of natural perspective, the better the result will be in the finished picture. F.P.

PERUTZ, OTTO, 1847–1922. German photographic manufacturer. Started as a chemist, bought in 1880 a chemical and pharmaceutical firm in Munich, and began manufacturing silver bromide gelatin dry plates based on Obernetter's formulae. After Vogel's discovery of sensitizing dyestuffs Perutz manufactured orthochromatic and later panchromatic plates. The first was the Vogel-Obernetter silver eosin plate (1884, still manufactured in 1955). Perutz also manufactured silver chloride plates for lantern slides, sheet films, and plates for aerial photography and for photo-mechanical work, antihalation plates. Introduced at an early date controlled processes, testing and research laboratories and built a film factory in 1922 from which issued 35 mm. films, fine grain films, X-ray films, etc. (*Denkschrift zum 75-jährigen Perutz-Jubiläum*, Munich 1955.)

PESTLE AND MORTAR. Heavy porcelain or earthenware bowl (the mortar) and a pear-shaped ball of similar material fitted with a handle (the pestle) used for grinding up chemicals to make a powder.

PETS. The photograph of a cat or a dog is not merely a representation of an animal; it is a picture of an individual. Every domestic pet has its distinct personality and, unless this is made clear, the photograph is a failure. The photographer must be prepared to study his subject and then set out to capture the attitude and expression that will convey its character in unmistakable terms. This sort of photography involves an appreciable amount of patience, understanding—and luck.

The Camera. Stand cameras are unsuitable; an animal cannot be expected to wait patiently in one place whilst all the necessary adjustments are made.

Many photographers who specialize in this field prefer a reflex camera, as the subject can be watched and focused on the screen right up till the moment of exposure. The reflex camera also has the advantage that it lends itself to use at a low viewpoint.

Others favour the miniature camera, because of its great depth of field and interchangeable lenses of large aperture.

There is something to be said for both, but no matter what camera is chosen, it should be equipped with a large aperture lens or lenses, so that it can be operated at reasonably fast shutter speeds. All controls should be easy to work and the camera generally should be handled without any apparent hurry or fuss that might disturb or excite the subject.

The Lens. A long-focus lens has the advantage of giving a large image of the subject from a relatively distant viewpoint and it helps to cut out distracting background objects. At the same time, it lacks the depth of field of the normal angle lens and calls for a lot of fidgeting with the focus if the subject is moving about. The best compromise is a lens with a focal length of rather more than the diagonal of the picture—e.g., a 5 cm. lens on a 35 mm. camera or a 4 ins. (10 cm.) lens on the popular 2¼ × 2¼ ins. (6 × 6 cm.) size.

The Sensitized Material. Only panchromatic materials should be used because it is absolutely necessary to show the colour and markings of the subject in true tone relation to the surroundings. Generally, only the fastest films and plates are worth considering, but if the lighting conditions are good enough and the subject is not likely to be restless, a medium speed panchromatic emulsion will give the best pictures. The fast film, having a coarser grain, will stand less enlargement. This, in its turn, calls for a closer viewpoint to give a bigger image, and very close viewpoints have a number of disadvantages.

Rabbits. No attempt should ever be made to photograph a rabbit in its hutch. The closed-in top and sides prevent effective lighting for modelling and texture. Its coat must look like fur; this means side-lighting and accurate focusing. A garden table and a suitably plain cloth held to form a background is better than working on the ground, unless the rabbit is white and will therefore stand out against it.

Closely-cut grass also makes quite a suitable setting, but a sky background is unnatural. The shutter speed should not be slower than 1/50 second, and the camera should be at the same level as the rabbit if possible. No filter is needed.

Birds in Cages. If the cage has a glass-edged base or internal hanging-mirror, these should be removed in case they catch the light and reflect back into the lens. It is best to stand or hang the cage in the garden. Backgrounds must be plain; dark-toned for light birds and vice versa. Watch out for the sun rays striking the plating on bars and fitments. Side or oblique backlighting is effective. A supplementary lens is needed if a long-focus lens is not available—this means shallow depth of field. A sky background is very suitable if it is well-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

filtered, i.e., by a 3× yellow, green or orange filter.

Photographing in a cage indoors in the window is possible but more difficult. If the camera is pointed directly out of the window, the bird and cage will become silhouettes against an over-light background. Arranging the cage at the side against curtaining, with the viewpoint from the other side is more effective. Direct sunlight will make snapshot speeds quite practicable with fast film.

Shutter speeds of not less than 1/100 second are recommended, although at times the bird may be sharply rendered at 1/50 second. Medium-speed film (panchromatic) is best, allowing for greater enlargement without coarse grain.

Mice. Tame mice are best photographed out of their cage. Outdoor lighting allows faster shutter speeds to be used. The camera must be as close as possible, and a supplementary lens is necessary to get an image of reasonable size.

The mice should be kept off the ground. Posing them on coat sleeves, the shoulder of a child, etc., gives size contrast and scale. Clothing must contrast in colouring and not be strikingly patterned. If the mouse is friendly with another household pet, particularly a cat, placing the two together on a box or table will give effective pictures. One or more helpers are needed for this.

Frontal or overhead lighting should be avoided. Shutter speeds of not less than 1/100 second are advised, and a ready trigger-finger to capture any fleeting action.

Goldfish. Photographing goldfish and similar species presents two major problems: focusing on the fish and coping with movement. The usual dodge is to lower a sheet of glass into the tank, 3 or 4 ins. away from the front, thus confining the fish to a narrow space within a pre-focused depth of field and also restricting rapid movement. Flash is best; the lighting should come from above the water and 45° to the camera axis.

A dark background is recommended and a shutter speed not less than 1/50 second if in sunshine or Photoflood lighting; synchronized flash will give opportunities to increase this speed.

Tortoise. The somewhat drab colouring of the tortoise needs careful choice of lighting and setting to convey its true character. Flat, sunless lighting is unsuitable; low-angle sunshine from the side is best. The camera should be at the same level as the tortoise if possible, but avoid long grass or camouflaging earthy settings. Rough towelling makes a good background and base if out of focus and not creased or folded. If the shell is wetted it will catch highlights and its ribbed markings will be emphasized.

Three-quarters-on or profile are easiest positions for successful pictures. No filter is needed; the shutter speed should be at least 1/50 second.

Although a tortoise moves very slowly, at the close distances necessary for photographing, such movement is equal to quite fast action farther away. P.J.

PETZVAL, JOSEF MAX, 1807–91. Hungarian mathematician. His calculation of a fast achromatic lens in 1840 played a very large part in the rapid development of portrait photography by the daguerreotype process. His portrait lens was of large aperture and achromatic for both optical and chemical rays. Also designed the Orthoscope lens 1857 for landscape and reproduction work. Both these lenses marked a great advance on any previous lenses in use and were widely used for half a century. Biography by P. Ermenyi (Halle 1903).

PETZVAL LENS. In 1840 Josef Petzval, a Hungarian, designed a lens for portraiture, and modern lens manufacturers still use his principle as the basis of many of their designs, especially for projection.

The original Petzval lens was made by combining two colour-corrected combinations—very like an R.R. lens with the negative elements facing inwards with a wide space between the two sets of glasses. It was generally used without a central stop and it gave apertures up to *f* 3·6. To-day modifications of the original form are used in the Dallmeyer portrait lens and in a number of wide aperture lenses for 8 and 16 mm. movie cameras. More complex types have been developed from it with apertures up to *f* 0·85 and are used for cine photography of the image on X-ray screens.

Petzval lenses are used more for projection than for anything else because over the relatively small field covered, the curved field of the Petzval lens is tolerable. In apertures up to *f* 1·5 or larger they are used for projecting lantern slides and all sizes of cine film. They are also used in epidiascopes.

The great drawback of the Petzval lens is its curved field. This restricts good definition to the centre and explains why Petzval lenses are used for projection, where only a narrow angle is wanted anyway, and for portraiture where, although the angle is greater, loss of definition away from the centre does not matter (and in fact may even add to the pictorial effect of the result).

See also: *Lens history.*

PETZVAL SUM. The radius of the curvature of field of a lens depends on the number of glasses making up the lens and their respective powers. This is expressed in terms of a number

known as the Petzval sum for that particular lens construction.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The Petzval number varies in magnitude and sign (plus or minus) with the lens construction; the greater the Petzval sum, the smaller the radius of curvature. The normal anastigmat has a positive Petzval sum, indicating that the curvature is concave to the lens. Some telephoto constructions have a negative sum—i.e., their curvature is convex to the lens.

pH. Alkalinity or acidity of an aqueous solution expressed numerically. Figures above 7 represent alkalinity; below, acidity.

See also: *pH value.*

PHENIDONE. 1-phenyl-3-pyrazolidone. Used as a developing agent.

Formula and molecular weight: $C_6H_5N(CH_2)_2NHCO$; 162.

Characteristics: White crystalline powder; acts similarly to metol, but can be used in much lower concentrations and does not tend to cause skin poisoning.

Solubility: Freely soluble in dilute alkalis, slightly soluble in water.

PHENOL. Carbolic acid. Used as a preservative and antiseptic in mountants, also as a developer for diazotype.

Formula and molecular weight: C_6H_5OH; 94.

Characteristics: White crystals with a characteristic antiseptic smell. The solid melts at 42°C (108° F.). Both the crystals and their solution in water attack the skin and must therefore be handled with care. Poisonous. Should be kept well stoppered, as the solid is hygroscopic.

Solubility: Fairly soluble in water.

PHENOSAFRANINE. Used in desensitizers and high speed developers.

Characteristics: Dark red powder (a complex dye).

Solubility: Fairly soluble in water.

PHILATELY. Philatelic photography—i.e., the photography of postage stamps—has three main purposes: for illustrating catalogues or descriptive articles, for investigating flaws and varieties, and for revealing forgeries and fakes.

Illustration. For catalogue or other illustration, stamps are copied at half to one and a half times natural size. Such photographs must convey as accurately as possible the tones and detail of the actual stamp. In black-and-white photography this means using a fine grain panchromatic film with a green correction filter for correct colour reproduction, or a suitable contrast filter to show up differences in tone of multi-coloured stamps.

The lighting set-up for straightforward stamp photography is similar to normal copying lighting, but on a smaller scale.

In some countries (e.g., the U.S.A.) there are legal restrictions on the photography of stamps. Reproduction is sometimes restricted to reduction smaller than $\frac{3}{4}$ natural size, or enlargement larger than $1\frac{1}{2}$ times.

Flaws and Varieties. Close-ups at twice to ten times natural size show up printing or engraving errors, varieties, and other small details which often make a specimen particularly valuable or interesting. To be really informative, such photographs usually show both the normal and abnormal stamp side by side for comparison. Two separate photographs taken under identical conditions may also be used.

Suitable filters may be employed to increase the contrast of the image, especially when photographing pale colours. In this case the filter colour is complementary to the stamp colour. Filters may also be used to eliminate coloured postmarks where these obliterate important parts of the design. The colour of the filter in this case is the same as the postmark. In many instances the postmark is black or so heavy in another colour that filtering can not be done very effectively.

Fakes and Forgeries. Copying on an enlarged scale often reveals mechanical repairs and erasures. For these pictures oblique lighting is used where it is necessary to show up surface irregularities.

Macrophotographs of this type should include a microscale or graticule to permit the exact size of details of the design or of overprints to be checked. Faked overprints are one of the favourite forms of stamp forgery.

Photography by ultra-violet rays is used to identify the paper of suspected counterfeits because most papers have their own characteristic fluorescence under this type of lighting. Chemical cleaning, removed postmarks, and repairs also show under ultra-violet radiation.

Infra-red photography is used to investigate faked overprints, postmarks, and even repainted parts of the original design. Photographs of the genuine pigments and those used in the forged specimen frequently look quite different taken through an infra-red filter on infra-red film. Experiments in photographing stamps by X-rays and grenz rays have also been made.

When examining suspected forgeries, a genuine specimen is usually photographed under the same conditions for comparison.

Watermarks. Photographs of stamp watermarks are taken on a high contrast film or plate to increase the low subject contrast.

Watermarks may be photographed by transmitted or reflected light. The former method gives the better results where the watermark is well defined, and the stamp a mint specimen. By using a filter of the same colour as the stamp, the stamp design can be practically eliminated. But a sheet margin gives the best reproduction of a watermark and this is always used if it is available.

For dealing with cancelled stamps, the most

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

successful technique is to lay the stamp face down in a black watermark tray and flood it with petrol. The watermark can then be photographed from the back of the stamp. This needs some care, as some inks are soluble in petrol, while on chalk surfaced papers the colours run on contact with water.

Ill-defined watermarks are naturally the most difficult to photograph, but they can usually be made to show up satisfactorily by being photographed by reflected ultra-violet radiation.

Watermark photographs taken from the back of the stamps have to be reversed left-to-right in printing to show the pattern the right way round. L.A.M.

PHOSPHORESCENCE. A number of materials possess the property of absorbing light of one wavelength and giving it out as light of another wavelength for some time afterwards. This property is known as phosphorescence. The luminous paint used for the hands and figures of watches and clocks is phosphorescent.

Reproduction processes have been formulated around the phosphorescent effect, using it to store an image which can be used to activate photographic layers placed in contact with it. A lantern slide can be printed on phosphorescent material by prolonged exposure.

It is possible to quench phosphorescence by means of infra-red radiation. This effect has been used to produce positive images from negatives projected by infra-red on to phosphorescent screens.

See also: *Negative-positive viewer; Viewers.*

PHOSPHOROPHOTOGRAPHY. Indirect method of infra-red photography based on the property of infra-red rays of being able to quench or reduce phosphorescence.

The invisible infra-red image—e.g., of a kettle of boiling water—is focused on to a glowing phosphorescent surface; it then creates a visible negative counterpart by reducing the glow in proportion to the intensity of the infra-red rays.

This negative image can then be photographed or transferred by contact on to ordinary sensitized material, giving in both cases a direct positive image.

Using the same principle it is possible to view a negative as a positive. The negative is projected by infra-red radiation on to a phosphorescent surface; where infra-red radiation (from the clear parts of the negative) falls, the phosphorescence is quenched, thus producing a positive image.

See also: *Heat recording; Viewers.*

PHOT. Unit of illumination corresponding to 1 lumen per square centimetre.

PHOTO. (Prefix.) (From Greek, phos, photos = light.) It is used in two senses:

(1) To indicate an association with light, as: photochemistry, the chemistry of the action of light; photogen, a kind of paraffin; photogenic (in physics), emitting light; photology, study of light; photolysis, movement of protoplasm under influence of light; photometer (whence -metric, -metry), instrument for measuring light; photophobia, morbid dread of light; photophone, telephone in which the connexion is made by a modulated light beam; photosphere, the luminous zone surrounding the sun or a star from which the light and heat are emitted; phototherapy, treatment of disease—e.g., lupus—by light rays; photosynthesis, the process by which plants form carbohydrates by the synthesis of water and carbon dioxide under the action of sunlight; phototropism, the bending of plants—e.g., flowers turning to face the sun—under the action of light.

(2) As an abbreviation of photography(ic) as: photo montage, phototelegraphy.

PHOTO-CALL. Full dress turn-out of the actors taking part in a theatrical performance, musical comedy, ice-show or similar entertainment, called by the management so that suitable scenes can be photographed for front-of-the-house and other publicity, for distribution to the press, and for the record.

See also: *Theatre.*

PHOTO-CATHODE. Layer of metallic or semi-conducting material which emits electrons when exposed to light. It may be prepared so that the electrons emerge from the side on which the light is incident (opaque photo-cathode) or from the opposite side (semi-transparent photo-cathode). Photo-cathodes are used in a wide variety of electron-optical systems, including image amplifiers, TV cameras, etc.

The emission process arises from the absorp-

SEMI-TRANSPARENT PHOTO CATHODE. Light reaching the semi-conducting layer is absorbed and electrons emitted instead. This takes place only if the photons (light quanta) have the right energy. A, sufficiently intense photon streams pass right through the photo cathode. B, photons are absorbed at the photo cathode and release electrons. C, if the energy of the photon stream is too low (wavelength too long) the light is absorbed but no electrons emitted. D,-semi-conducting photo cathode. E, transparent (glass or quartz) base.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tion of a quantum of light (photon) by an electron in the material, which thus gains the energy of the photon. The electron is then able to move through the material, and if it reaches the surface with sufficient energy it can escape. The minimum energy for escape is characteristic of the material, and the photon energy must exceed this if electrons are to be emitted. Consequently a photo-cathode responds only to light of wavelength shorter than a characteristic value, called the photo-electric threshold of the material. Only a few metals and semi-conductors have thresholds in the visible and infra-red.

The sensitivity of photo-cathodes which respond to visible light is often quoted as the current emitted per lumen of white light from a tungsten filament at colour temperature 2870°K. The sensitivity of antimony-caesium cathodes is usually between 30 and 90 micro-amperes per lumen. Even higher sensitivity is obtained from a combination of antimony with sodium, potassium and caesium (multi-alkali photo-cathode). The only known photo-cathode with useful infra-red response is a combination of silver, oxygen and caesium. The threshold lies near 12,000 A, and the sensitivity may be 50 microamperes per lumen. W.L.W.

See also: *Image amplifier.*

PHOTOCHEMISTRY. Study of chemical reactions influenced by the action of light.

The photochemical reaction of main importance in photography is the decomposition of silver halides by the action of light. Other reactions which involve the action of light are:

(1) The reduction of certain ferric salts to ferrous (as in the various iron printing methods such as blue-print process and others).

(2) The tanning of bichromated gelatin or glue (as in the carbon and oil processes and also in a variety of photomechanical methods of reproduction).

(3) The bleaching of dyes (as in diazotype) and a number of further reactions of little photographic application.

Among the principles established as laws of photochemistry, the following are of interest:

The Grotthuss-Draper law states that only those wavelengths of light which are absorbed can cause chemical changes in a system. In the decomposition of silver halide, short wavelengths are the most active. The light rays need not necessarily be absorbed by the reacting substance, but can instead activate certain photo-sensitizers which absorb different wavelengths from those utilized by the photochemical reaction. The energy of the activated photo-sensitizer is then transferred to the non-activated molecules of the reacting system, making the latter sensitive to the wavelengths absorbed by the sensitizer. This is the basis of the sensitization of photographic emulsions to green and red light with help of certain dyes.

The Bunsen-Roscoe law states that the amount of chemical change produced is proportional to the quantity of light absorbed (i.e., its intensity multiplied by the time for which it acts). In practice the change also depends on the intensity of the light. The deviation from this law is the reciprocity failure.

It is now accepted as postulated by Planck, that radiation is emitted and absorbed in definite units or quanta. Einstein's law of photochemical equivalence in its original form stated that the number of molecules reacting should be equal to the number of quanta absorbed. (A quantum of energy is equal to the frequency of the radiation multiplied by a constant known as Planck's constant.) In practice, not every quantum of radiation absorbed necessarily causes a photochemical reaction in a molecule, and the effectiveness of the light absorbed is often expressed in terms of the quantum efficiency of the reaction. This quantum efficiency is the ratio of the number of actual molecules reacting for a given amount of light energy absorbed, to the number which could theoretically react.

In a photographic emulsion each silver halide grain becomes developable when sufficient light has been absorbed to reduce an adequate number of silver halide molecules to produce a sensitivity speck on the silver halide crystal. The primary quantum efficiency of the reaction is nearly 1, and nearly as many silver atoms are liberated as quanta are absorbed. But to produce an effective sensitivity speck, each crystal needs about forty quanta of light and the quantum efficiency of the whole process is in the region of 2½ per cent per crystal. With a quantum efficiency of 100 per cent, i.e., one quantum per crystal, the material would have reached its maximum theoretical speed. This is around 10,000–20,000 ASA for a fairly coarse-grained emulsion. No faster photographic emulsion is therefore ever likely to be produced and it is improbable that even this limit will be reached with silver halide emulsions. L.A.M.

Mees (New York); *The Chemistry of Photographic Materials*, by G. F. Duffin; *Processing Chemistry*, by L. F. A. Mason; *Chemical Analysis in Photography*, by G. Russell (all London).

PHOTOCHROMISM. A reversible colour change induced by light energy.

PHOTO CONDUCTOR. Electrical semi-conductor which changes its resistance when exposed to light or certain other types of radiation. Usually the resistance is very high in the dark (so that the conductor becomes a virtual insulator) and drops according to the intensity of the exposing light. Photo-con-

ductors (also known as photo-resistors) are used in various forms in exposure meters, electronic image control devices, etc.

See also: *Electro-luminescence; Photo-electric cell.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PHOTO COPYING. Fundamentally any document, microfilm or office copying process utilizing light sensitive materials. More specifically the term is generally applied to direct office copying processes.

See also: *Diffusion transfer; Document copying.*

PHOTO-DRAWING. Engineering or architectural plan produced on a photographic background of the object to be detailed. Photo-drawings can present design intentions for modifications to existing installations against a realistic and detailed background. In contrast with conventional plan and elevation drawings, photodrawings provide a clearer visualization of design and working instructions.

Production. The production of photo-drawings involves four main steps:

(1) The taking of photographs to show all relevant details of the existing situation;

(2) Printing on to a film or translucent paper to the desired scale;

(3) The film-print either itself forms the drawing sheet or is taped on to a sheet of drawing material and the draughtsman superimposes a simple perspective view of the engineering work that is to be done;

(4) Reproduction of the drawing, combined with the photograph. This is made on ordinary inexpensive dyeline paper which can be handled in the customary rough manner.

Photo-drawings save drawing time because the photograph shows details that would otherwise have to be measured and drawn as background before new design information can be inserted; they make the job easier to understand and visualize.

Camera angles are selected to permit a properly orientated perspective drawing to be superimposed over the photograph. The scale should be as large as possible to avoid congestion of the drawn work.

The film-print is made by enlarging on to transparent or translucent film or paper. To preserve tonal gradation of the photograph in the dyeline print the contrast of the film-print is kept very low. Contrast is more easily controlled by printing through a half-tone magenta contact screen on to lith-type film. The average density of the film-print must be adjusted to permit good reproduction of the photograph and the drawing simultaneously. When the film-print is made on a base the back of which is treated to provide a drawing surface it can itself be the drawing sheet.

Film-prints can also be made on clear film which can then easily be taped on to the back of tracing paper or film in the desired position.

Application. Photo-drawings are useful to show modification to piping installations, design changes on mechanical and electrical equipment, site clearance planning, structural and architectural modifications, illustration of assembly and maintenance instructions, making perspective drawings for detailing three-dimensional scale models, and a variety of other uses for communication of design and dimensional information.

Non-Perspective Photography. When three-dimensional scale models of manufacturing plant, or prototype models, are used as design tools, photo-drawings can be used to transmit dimensional information in the model to sub-contractors, constructors and fabrication teams. In such cases the natural perspective in ordinary photographs can be undesirable. Perspective parallax is reduced by photographing the model with an extremely long focus lens from distances of from 50 to 100 feet. Completely non-perspective presentation is achieved by using a camera with a telecentric mirror-lens system. The image is then formed only by those light rays reflected from the object which are parallel with the optical axis, so that all planes of an object are reproduced at the same scale and the projection if strictly orthogenal. Areas larger than the field of view of the camera, which is restricted to the diameter of the mirror, are photographed in sections. Contact prints on dimensionally stable paper are then assembled to make a mosaic covering the entire object. The technique of photodrawing is used for reproducing the mosaic, when specifications, dimensions and instructions are added prior to duplication by dyeline printing. R.F.

PHOTO-ELASTICITY. Technique of determining, with the aid of light, the stress distribution in bodies under complex systems of loading.

Plane polarized light is passed through a transparent model of the object whose stress distribution is required. The model is subjected to loads proportional to the loads applied to the real object and when viewed through a suitable polariscope a pattern of light and dark lines is observed which can be recorded photographically. In two dimensions the stress condition at any point can be defined by the magnitude and inclination of the two principal stresses and it is possible to determine the stress distribution in the model from these lines.

Two types of lines are observed:

(1) Isochromatic lines, which are coloured when using white light and are contours of stress. The zero stress line is always black.

(2) Isoclinic lines, which are superimposed on the isochromatic lines, are always black, and give the directions of the principal stresses.

Optical Theory. The phenomenon depends upon the fact that an isotropic transparent material becomes double refracting when

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

REFLECTING POLARISCOPE FOR PHOTO-ELASTIC COATING TECHNIQUE. The light rays from the source A pass through a polarizer B and a quarter-wave plate C to the metal surface E being investigated. This surface is coated with a reflecting layer D and a photo-elastic coating material F. The latter distorts with the component being tested. The light rays then pass through another quarter-wave plate F and the second polarizing filter (analyser) G.

stressed. Plane-polarized light passing into such a material is split up into two components vibrating in the directions of the principal stresses and travelling through the material at different velocities. If these components are recombined after passing through the model they will interfere if out of phase and produce the isochromatic lines observed.

When the plane of the incident polarized light is coincident with the direction of one of the principal stresses the light will be cut out on recombination in the analyser which is "crossed" (i.e., its plane of polarization at right angles) with respect to the polarizer. A black isoclinic line is thus formed.

The Model. The model is often a section of the object under investigation, the sensitivity of the technique increasing with model thickness. Limitations are set on a model thickness due to difficulties in obtaining constant stress distribution throughout the thickness of the model. A suitable thickness is about ¼ inch.

The material used for the models now is generally one of the epoxy resins such as Araldite CT200. The surface of the model must be polished and areas of the sheet material chosen which are free from initial stresses. Care must be exercised in fabrication of the model that no built-in stresses are produced. If such stresses are present they may be reduced by an annealing process.

Polariscope. A suitable polariscope for investigating and photographing the stress distribution in models consists of a small light source situated at the focal point of a condenser lens. The parallel light emerging from this lens passes through the polarizer, which can be a non-optical quality polarizing sheet, to the model. On emerging from the model the light passes through the analyser which is an optical quality polarizing sheet and then on to a second condenser lens at whose focal point the camera lens is situated.

This second condenser should be corrected for spherical and chromatic aberration although good photographs can be obtained within the central part of the field of view with a simple lens. With the second condenser lens of 12 or 18 ins. focal length and 5 or 6 ins. diameter, and a quarter- or half-plate camera, it is easy to obtain a record of the model which is approximately full size. However, this polariscope may be used with almost any size camera, including miniature cameras using 35 mm. film or 16 mm. cine cameras.

The isoclinic lines can be removed by interposing quarter-wave plates at each side of the model; the light then passing through the model is circularly polarized and the isoclinic lines disappear due to the non-directional character of the light.

With the polarizing sheets and quarter-wave plates in position the condenser lenses need not necessarily be free from residual stresses.

Photographic Materials and Technique. For photographic purposes, a compact source mercury vapour lamp with a green filter is generally preferred and orthochromatic negative material can be used with this light. Alternatively a bank of sodium lamps can be used without any filter or condenser lens but the material must then be panchromatic.

The exposure is adjusted until the light lines of the pattern show a slight density on the negative. The development time of the negative should be increased by 25 or 50 per cent over that recommended for normal subjects in order to obtain a result of sufficiently high contrast. The prints are made on an appro-

POLARISCOPE FOR PHOTO-ELASTIC STRESS ANALYSIS. The model, made of a suitable resin or plastic, is placed between crossed polarizers, and photographed by a beam of transmitted light. A, light source. B, filter for monochromatic light. C and I, condensers. D, polarizer. E and G, quarter-wave plates to remove isoclinic lines by circularly polarizing the light. F, scale model of object or structure to be tested for stresses. H, analyser (second polarizer). J, camera.

priate high-contrast grade of white, smooth glossy, bromide paper.

Three-Dimensional Stress Analysis by Stress Freezing. Stresses in three dimensions can be analyzed by using certain high polymers (such as Araldite CT200) that retain a stress pattern permanently after they have been subjected to a heating and cooling cycle whilst under load. The method is to construct a fully sealed model of the part to be examined, to subject it to the thermal cycle and, when it is cold, to cut slices from it for examination in the polariscope. The photo-elastic pattern gives the stresses in the plane of the slice.

Photo-elastic Coating Technique. Another method consists of attaching a thin layer of polymer sheet to the surface of a metal part. A reflecting layer is interposed at the metal surface and the effect of loading the part is observed with a reflecting polariscope. This method has the advantage of being applicable to actual hardware. It shows the strains in the metal and can be used for strain above the elastic limit of the metal. G.C.L. (A.F.C.B.)

PHOTO-ELECTRET. An electret is an electrically isolating body with persistent internal polarization, i.e. it carries electric charges of opposite sign at two opposite faces. A photo-electret is an electret (formed by subjecting it to an electric field and simultaneous uniform illumination) the polarization of which will disappear imagewise on exposure to radiation of suitable wavelengths. The electrostatic image can be revealed by dusting with a suitable powder. It is also possible to form the photo-electret image by applying an electric field together with the irradiation image, when the surface will be charged more strongly the stronger the exposure.

PHOTO-ELECTRIC CELL. Device which either generates, or produces a change in the value of an electric current when exposed to light. The type mostly used in photography is known as a barrier layer cell and in its basic form it consists of an iron disc coated with a layer of selenium over the top of which is applied a film of gold or platinum thin enough to allow light to pass through.

When light falls on the front of the cell, it creates a potential across the boundary between the selenium and the gold. When the photo cell is incorporated in a light meter, this potential is connected to a sensitive micro-

COLOUR RESPONSE OF CELLS. A celeium cell (Se) has its maximum sensitivity in the yellow green region, but responds appreciably also to shorter wavelengths (heavy broken curve). By filters the sensitivity can be restricted to approximately the response of the eye (thin solid curve) but would then appreciably differ from the relative sensitivities of a panchromatic film (thin broken curve). The cadmium sulphide cell Cds follows the eye curve more closely, but also responds to radiation well into the infra-red radiation (heavy dotted curve).

ammeter. The meter needle is thus deflected in proportion to the strength of the light falling on the cell and can therefore be calibrated in terms of the exposure required under that particular intensity of illumination.

Barrier layer cells are self-generating so that there is no need to provide them with an energizing voltage. This enables them to be built into remarkably compact exposure and colour temperature meters, including types incorporated in cameras.

The second type is the photo-conductive cell. This consists of a layer or area of cadmium sulphide between two electrodes, which acts as a semi-conductor. In the absence of light the cadmium sulphide has a high electric resistance, which drops when light falls on the cell. A current flowing through the cell therefore varies according to the light reaching the latter, and a microammeter connected to the circuit can indicate the light strength and can also be calibrated in terms of the exposure required.

A photo-conductive cell needs a battery or other power source to provide the current in the circuit. In modern cadmium sulphide cells—the most popular type of photo resistor used in exposure meters—the usual power source is a mercury miniature cell. This has a life of one to two years.

The cadmium sulphide cell is particularly compact—usually even smaller than a barrier layer cell—and is thus suitable for building into cameras. The sensitivity of the cadmium sulphide cell is appreciably higher than that of a barrier layer cell, and exposure meters of this type can therefore measure very much lower lighting levels. The cadmium sulphide cell is however subject to fatigue effects, and after exposure to strong light does not regain its full sensitivity until after a certain rest period (which may vary from several minutes upwards). Owing to the independent current supply an exposure meter of this type is more versatile for the direct control of camera settings.

A third type of photocell consists of a glass envelope containing a cathode coated with a light-sensitive metal such as caesium or potassium, and an anode which serves to collect the electrons emitted. Sometimes the cathode is formed by a coating on the inside of the bulb. The bulb may be evacuated, or may contain a trace of an inert gas such as argon.

A steady potential of about 90 volts is maintained between the electrodes from an external supply, and under these conditions light falling upon the cathode causes a current to flow to the anode. In the case of a gas-filled bulb this current is intensified by molecular collisions. Over a given range, this current is proportional to the intensity of the light; it can be amplified and used in a number of ways. Photocells of this type are used in the sound head of sound film projectors, for optical triggering of camera shutters and for automatic exposure control in bulk film printing machines.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PHOTO-ELECTRIC METER. Exposure meter utilising a photo cell which either generates an electric current when light falls on it, or changes in resistance to a current flowing through it. In either case the output current may work a microammeter to give a reading of the lighting level or of the exposure required; or the current from the photo cell can also be used to set—directly or indirectly—the exposure controls of the camera.

Photoelectric systems are also used in semi-automatic printing and enlarging equipment.

PHOTO-ENGRAVING. Term originally used to mean any process based on photography for the production of a printing surface. It is now generally applied in a more restricted sense to the production of a relief printing surface by a process based on photography.

See also: *Photo-etching; Photomechanical reproduction.*

PHOTO-ETCHING

Process of producing photographically a resist image which protects a surface (e.g. metal) from an etching medium during subsequent treatment.

The etching of patterns or designs into metal by means of acids capable of dissolving the metal is an age-old art. Before the advent of photography the metal was as a rule coated all-over with a suitable acid resistant composition, such as a mixture of beeswax and bitumen and the design was then scraped into the coating by hand or by suitable ruling machinery. The scraped parts were thus bared from etch ground and open to the attack of the acid. After etching, the wax was removed.

Soon after the invention of photography methods were developed to replace the hand or machine engraved etch stencil in wax by a stencil produced by photographic processes, the photo-stencil.

Photo-Resists. The essential requirement for making a photo-stencil is the photo-resist, i.e. a light-sensitive material which can be coated in a thin layer on metal, glass or plastics. The photo-resist layer is exposed to light under a negative, usually but not always produced by photography. The non-exposed areas protected against light, remain soluble in suitable solvents and are removed in such a solvent. The exposed areas become insoluble, forming the photo-stencil which protects the metal image-wise against being attacked by the etching fluid.

Photo-Engraving. Photo-etching by means of photo-stencils is universally used for the production of line or half-tone blocks for letterpress printing and intaglio copper plates or cylinders for gravure. However, even planographic plates, e.g. for offset printing, are quite often etched (deep etch process).

Etching of letterpress blocks in the classical manner raises one problem. The etching, particularly with line blocks, must reach a considerable depth. During the necessary prolonged etching process the acid not only etches in to the depth but it also attacks the metal from the sides of the recesses formed during etching. It gradually widens the etched area, a phenomenon termed under-cutting. Until quite recently this undesirable feature was counteracted by etching in stages. Between each stage the already formed walls of the etching were in some way protected against further attack of the acid during the next etching stage. One of the methods is to powder the etched portions with a suitable resin (e.g. dragon's blood) in such a manner that the resin adheres only to the walls of the etching but does not cover its bottom. This is brought about by a delicate brushing procedure.

The more recent powderless etching methods eliminate the need for the cumbersome powdering or similar procedures. Here etching fluids are used in conjunction with certain organic compounds which form a liquid etching emulsion. Using suitably constructed etching machinery it appears that during etching the organic constituents of the etching fluid are preferentially deposited on the walls of the etched recesses, acting thus to some extent as protection.

By far the largest application of photo-etching is still photo-engraving devoted to the production of printing formes. During and since the end of World War II photo-etching methods have however extended to new fields of increasing importance in mechanical and electrical engineering, such as chemical milling, printed circuit production, etc.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Nameplate Manufacture and Decoration of Metals. Increasing quantities of nameplates are nowadays produced by etching through photo-stencils. On the whole the technique follows the well-established lines of that of block making. However, aluminium and its alloys and anodized aluminium which are not used for block making sometimes require special treatment.

The decoration of metal surfaces by photo-etching is applied to surfaces of all dimensions. So entire panels for lift doors are commercially produced by photo-etching as well as minute dials for miniature watches.

Chemical Milling. Photo-etching can sometimes replace mechanical milling in the manufacture of engineering components. Its object is usually the decrease of weight of metal sheets by removing part of the metal thickness, leaving a structure of ribs of the original thickness intact. This is of special interest for the aircraft industry. The metal in question is usually aluminium and its alloys and the procedure is said to be faster and more economical than mechanical milling. A depth of etching to a quarter of an inch is not unusual.

The term chemical milling is often also applied to the manufacture of perforated metal parts although a distinct term would be desirable.

The important difference between chemical milling in its narrower sense and the manufacture of perforated metal parts by photo-etching lies in the fact that in the latter case the metal in question is etched right through its entire thickness, leaving the perforated metal part free with its desired, frequently quite complicated, contours.

Usually, in order to obtain inner and outer contours of high definition the metal in question is photo-etched from both sides of the sheet. This requires the production of photo-stencils in perfect register on both sides of the metal. So two photographic negatives have to be produced and exactly located relative to each other.

Perforated metal parts, such as springs, electrical contact pieces, sieves, etc., are, of course, produced in huge quantities by stamping them out by means of dies. The newer photo-etching techniques have several advantages.

Dies are very expensive. One does not usually have them cut until the exact shape of an intricate metal part has finally been defined. However, in a time of rapid development it is highly desirable that prototypes of the metal part in question can be produced in small or medium quantities at relatively low cost and without undue delay. It is here that photo-etching scores.

Secondly, die-stamping invariably leaves a burr at the contours of the metal part and the removal of this burr is sometimes a costly additional operation. Also, die-stamping imparts undesirable internal stresses to some metals. Photo-etching, on the other hand, is completely free from these features.

Almost all metals and alloys can be photo-etched, including for instance molybdenum and tantalum, metals which are often a trial for even the hardest dies. Perforated metal parts up to a thickness of 0·04 ins. have successfully been photo-etched and in thinner metal sheets intricate designs have been produced which one can hardly hope to obtain by stamping.

Printed Circuits. There is nowadays hardly an electronic instrument in which the formerly used wiring connections are not replaced by a printed circuit. As the name suggests, printed circuits are to some not inconsiderable extent produced by printing, e.g. by silk screen or offset methods, the ink serving as etch resist. A large and increasing proportion of them is, however produced by photo-etching, as the design of circuits becomes increasingly complicated and the demands on accuracy and definition of the elements of the design grow.

The conventional basis for a printed circuit panel is a copper laminate, i.e. a copper foil, 0·001 ins. thick or more, which is laminated to a non-conductive base, such as a plastic sheet.

The copper surface is coated with a photo-resist. After exposure to light through the negative of the required circuit pattern and processing, the resist forms a photo-stencil. Through this stencil the copper is etched. In contrast to photo-engraving, the metal is etched right through its entire thickness, leaving the design of the conductive circuit on the bared insulating plastic.

Also, instead of a single or a few blocks made from a specific design for the printing press, hundreds or thousands of printed circuits are produced from one and the same pattern. Consequently the whole procedure is mechanized, beginning with the cleaning procedure of the copper surface and ending with the etching stage and the removal of the photo-stencil.

Owing to the thinness of the copper foil there is comparatively little under-cutting but as the demands on quality increase research is on the way to minimize under-cutting by photo-etching.

Transistors and Micro-miniature Circuits. The basis of most transistors is a thin wafer of a semi-conducting substance, such as silicon or germanium, an inch square or even less. From such a wafer a number of transistors, say 100 or more, are produced, i.e. the actual design of each transistor is repeated many times on the wafer.

Frequently the multiple design is produced on the wafer by evaporation of metals through extremely fine masks (evaporation masks), which are laid on the wafer.

Alternatively vacuum deposition is done through a photo-stencil produced on the surface of the wafer.

There are, however, frequent cases where

either a metal, evaporated over the entire surface of the wafer or the material of the wafer itself is etched image-wise through a photo-stencil.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

According to the nature of the metal or to the material of the wafer itself etch fluids of various compositions have to be used, ranging right up to mixtures of hydrofluoric acid with other strong acids as for instance nitric acid. Owing to the minute dimensions of the design and to the nature of the acids, photo-stencils of high acid resistance and of very high definition have to be produced on the surface of the wafers.

Similar methods are applied to the production of micro-miniature or miniature circuits. Such circuits might consist merely of an array of conductive lines, when it is a miniaturized version of a printed circuit. However, owing to its small dimensions and by electronic consideration and requirements the comparatively crude copper-foil-laminate of the printed circuit manufacture cannot any longer be used. Instead, a thin layer of a highly resistant and adherent metal or alloy, is evaporated on glass of suitable properties and the design is photo-etched in this metal.

Other kinds of micro-miniature devices incorporate not only conduction lines but also intrinsic parts of an electronic circuit, such as resistors and capacitors.

The ever increasing demands on smallness of individual devices and on highest definition present problems concerning properties of photo-resists and photo-etching as well as of photo-emulsions and lenses unheard of a few years ago. E.E.L.

PHOTO FINISH CAMERA. Special camera for producing a photographic record of the order of arrival of competitors at the finish of a track race.

The camera is sighted along the finishing line and the film is moved in the opposite direction to the race at a speed which is approximately equal to the movement of the image across the focal plane. The image is therefore more or less stationary with respect to the emulsion surface. The film is exposed through a fixed vertical slit which coincides with the image of the finishing line formed by the lens.

PHOTO-FINISH CAMERA. The film moves past a slit behind the lens, aligned with the finishing line of the race. The film movement is adjusted to the speed of the race. The image of each horse starts to build up the moment the horse passes the finishing post. A, finishing post. B, lens. C, slit. D, take-up cassette. E, film. F, driving drum. G, feed cassette.

Before the leaders arrive, the film simply records a continuous blur left by the stationary image of the finishing line. As soon as the first contestant starts to pass over the line, it begins to record its image on the moving film from the nose backwards along the length of the body. Since the image and the film are moving at the same speed, the record is sharp, and it builds up to form a complete picture as the rest of the field crosses the line.

A time scale in $\frac{1}{100}$s of a second along the film directly shows the winner's time, i.e., the instant at which he crosses the finishing line of the course.

A white cursor line is introduced into the photograph when printed so that the position of the winner in relation to near by runners can be clearly seen. It is common practice now to also have a mirror facing the camera on the far side of the track so that, as the camera points at it from an angle, a second (reflected) image of the runners is also recorded; this helps in distinguishing the positions of the leaders.

Most photofinish installations are now arranged in such a way that the result can be projected as an enlarged negative image directly from the camera room on to an adjustable viewing screen in the Judge's box. The negative can be prepared for projection in 20–25 seconds from the end of the race so saving valuable time by comparison with the earlier procedure of making prints for the judge. The negative is in no way impaired by projection and prints can subsequently be made for display to the public.

PHOTO FINISHING. Work of the commercial establishments which develop and print amateur roll films in quantity for the retail photographic trade. Also known as D. & P. (Developing and Printing).

See also: *Wholesale photo finishing.*

CC-0. Vidyasagar Digital Preservation Foundation, Chandigarh

PHOTOFLOOD. Electric filament lamp designed to provide a high intensity source of artificial lighting for a relatively low current consumption. This is done by designing the lamp so that it will be over-run when used on normal household voltage.

Photofloods form a cheap and convenient form of lighting for indoor photography and cinematography.

The brilliance of the light is purchased at the price of its working life; Photofloods last about two hours when switched on for no more than a minute or two at a time. Run continuously, they burn out much sooner. Large photoflood lamps may have a burning life of around 6–8 hours.

The working life can be extended by using a dimmer instead of a switch so that the voltage can be applied gradually.

Another life-saver is to run two Photofloods in series-parallel, switching them on in series for focusing and arranging the subject, and changing to parallel for the exposure.

See also: *Filament lamp; Light sources; Series parallel.*

PHOTOGALVANOGRAPHY. A photomechanical printing process patented by Paul Pretsch in 1854. As modified in 1856 it was somewhat akin to photogravure, giving true halftones. A relief picture in bichromated gelatine was used to produce a guttapercha intaglio mould. From the mould, a copper matrix in relief was produced by electrotyping. Finally by a further process of electrotyping, a thick intaglio copper plate was made, from which the proof was printed. The entire process took about six weeks. 400–500 good impressions could be printed from the plate, and a considerable number of plates could be obtained from the matrix.

Pretsch came to England to exploit his invention, and the first number of *Photographic Art Treasures* appeared in November 1856—the first British publication of photographs in printing ink.

PHOTOGENIC. Photogenic drawing was term used by W. H. Fox Talbot to describe his earliest photographic process "by which natural objects may be made to delineate themselves without the aid of the artist's pencil". In modern usage photogenic is an adjective borrowed from the French indicating subjects, more generally people, who are particularly easy to photograph well, possibly because they may combine ease in front of the camera with well-proportioned or expressive features.

PHOTOGRAM. At one time the term photogram was used in a limited way to describe the consciously artistic photograph as opposed to the mere mechanical record. Nowadays, however, the word is generally reserved for pictures of an abstract kind which, though made on photographic material, are created without the use of a camera.

History. In its simplest form the photogram is a direct shadow pattern formed by flat objects placed on the sensitive material during a brief exposure to light, and the image thus produced is a negative silhouette—white on a grey or black ground. Josiah Wedgwood (1730–95), at the end of the eighteenth century, found that he could reproduce the form of a leaf in this way on paper bathed in silver nitrate, but his "sun prints" were not permanent for he knew of no way of desensitizing the paper afterwards. Later Talbot made permanent "photogenic drawings" of plant forms and pieces of lace in the same way, and by using the first print as a paper negative he was able to turn the image into a positive silhouette.

These experiments were, however, merely stages in the early development of photography and it was not until many years later that the aesthetic possibilities of these simple shadow patterns began to be appreciated. Inspired by cubism, Christian Schad in 1918 elaborated the technique by placing strips of torn paper, etc., on the sensitive material to produce overlapping shadow patterns that rather resembled the collages made by the painters. Further developments came in 1922 when Man Ray and L. Moholy-Nagy made their "rayographs" and photograms, using not merely opaque flat objects but also three-dimensional and translucent ones and recording the shadow patterns of varying sharpness produced by them.

Since then, the technique has been further extended and the word photogram has come to be used not merely for these comparatively simple shadow pictures, but for all sorts of abstract pictures made on photographic material by any method at all—including the deliberate (or sometimes, no doubt, accidental) fogging or staining of the print. In fact, anything is fair in photogram making and no method is barred so long as no camera is used. But there would seem to be no reason why one should not project a camera-made negative of a suitably abstract kind to form part of the photogram image, so it is clearly impossible to draw a sharp dividing line between the photogram and, say, the abstract photograph.

Method. The making of a photogram is an uncertain business: it is not easy to tell beforehand how it will turn out, but therein lies the fascination. After a series of dull and disappointing results, the surprisingly beautiful effects that come quite unexpectedly can more than make up for the failures.

Films or plates can, of course, also be used; but large ones are costly and small ones are limiting. But there is the advantage that they can be enlarged to make positive versions (or via contact transparencies, enlarged negative prints also). But photograms made direct on thin paper can also be duplicated by using the

original as a paper negative. A certain amount of the texture of the paper will be evident in the photogram, but this will not usually detract from the result and may, indeed, enhance it.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Materials. Literally anything may be used to form the shadow patterns—e.g., paper of varying degrees of translucency, cut or torn to suitable shapes, coiled or crumpled paper or Cellophane, bits of gauze, perforated zinc, bent wire, string, thread, hair, a feather, a watch spring, an electric bulb, or a kitchen implement. Solid objects, if light in tone, will, when not in all-over contact, introduce a partial greying of the white shadow pattern where the light has crept in or is reflected from the underside.

Polished objects will throw out spots and lines of light and, if the exposure is short enough to leave the background fairly light, these will show up in black. Interesting effects of this sort can be got by using strips of tinfoil, curled or twisted in various ways. Somewhat similar effects are produced with glass-ware—e.g., a cut glass stopper, the neck of a broken bottle, fragments of glass, a condenser lens or transparent crystals. These reflect and refract the light in quite unexpected ways, producing lines and splashes of black through both white pattern and background.

The articles may be placed direct on the bromide paper, or they may be arranged on a sheet of glass with a sheet of white paper under it, so that the effects can be to some extent planned and studied. The glass can then be gently lifted and the bromide paper slid under it. This makes it easy to run off several prints, and to alter the arrangement without starting afresh each time, although the objects in question will never record completely sharply by this method. For maximum sharpness the glass used should be as thin as possible, and the exposure should be made under directional illumination, such as is given by an enlarger which is focused onto the bromide paper.

Lighting. Any kind of light source can be used, from a match to a small spotlamp. The character of the shadow shapes will depend on how concentrated the light is, on its distance from the objects and the angle at which it strikes. An electric torch bulb—preferably without reflector—makes a very useful tool because it can be used at close quarters at any angle, either held in the hand or arranged on some improvised stand.

Softer outlines will be created by an ordinary pearl lamp, but this will have to be used farther away or exposures will be too short to control accurately.

For sharp clear-cut outlines the material may be arranged under the enlarger, with the enlarger focused sharply on the bromide paper; a baby spot will produce similar sharp effects and can be applied from any angle, but unless it is very small indeed it will have to be a good way off.

More complex patterns with cross shadows result if two or more lights are used, or the same effects can be got by making multiple exposures with a single lamp in different positions. Curious ghostly effects can be produced by keeping the light moving during exposure.

Endless variations in the shadow shapes can be made by changing the angle of the lighting. This is especially so if the articles stand up well from the glass and are only in contact with it at certain points. With low slanting light the shadows stretch out and widen into fantastic shapes. Bent wire and glass articles are particularly suitable for this treatment. Vaguer patterns are produced if the objects are raised some distance above the paper—e.g., by a second sheet of glass.

Soft all-over patterns can be introduced with netting, or by sprinkling very small articles—say hypo crystals or sugar, or drops of water—over the raised glass.

Variations. The pattern need not, of course, be confined to white shapes on a grey or black ground: by interrupting the exposure and then taking away some of the articles, their shadows will be greyed to a depth of tone depending on the length of the further exposure. When the articles or their shadows overlap this method is extremely effective. The tone of the background also can be varied by holding back parts, as in enlarging. A photogram may be in bold black-and-white or, at the other extreme, in white and pale greys.

And as all is fair in photogram making, the print can be partially fogged or even deliberately stained by exposing it to light before it is completely fixed. Films or plates can also be fogged during development to cause solarization of the image.

There is still another way of making photograms with the enlarger not yet mentioned: it might be called the method of the "hand-made negative".

Cut-outs and various small articles are formed into a design on a small piece of glass which is slid into the position usually occupied by the negative carrier of a vertical enlarger.

Obviously the articles have to be small and with expressive outlines, and many if not all, should be transparent in some degree—e.g., pieces of very thin paper, Cellophane, old film, a mica washer out of an electrical fitting, a small feather, hairs, thread or gauze. Unfortunately, many enlargers are unsuitable for this technique because there is not a big enough gap for such a thick "negative" to be slid into place.

A further extension of this idea which has been applied effectively by some artists is literally to draw the negative by etching on a blackened plate or by applying pigment to a clear plate, and printing the result. H.v.W.

PHOTOGRAMMETRY

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Science of making measurements from photographs. Through such measurements taken on aerial photographs it is possible to construct maps and obtain a great deal of information concerning the topography, vegetation and other feature depicted on the photographs. The majority of this type of photography is taken from aircraft using special wide-angle cameras, but photographs taken on the ground are widely used in other applications of this science, namely, in the fields of architecture, deformation surveys, biology and medicine.

By the application of photogrammetric principles to the central perspectives (photographs) obtained, it is possible to carry out the plotting and/or recording of the required data within a great range of scales (e.g. maps are frequently produced from scales of 1 : 100,000 up to 1 : 500) whereas using close range, macro and micro photography scales extending to 100 : 1 can frequently be obtained.

There is little which is basically new in either photographs or their measurement. The photogrammetrists' concern lies largely with the geometrical solution of pairs of perspective views, solid geometry, binocular vision and the accuracies obtainable therefrom; and present techniques are the result of a general advancement in the accuracies obtainable rather than upon new principles.

Despite the development of basic ideas, the practical application of aerial photogrammetry could not develop until the introduction of the aeroplane and its aerial camera, and the plotting apparatus designed for use in analysis and plotting.

As mentioned, photogrammetrical surveys are carried out on various scales, according to the work in hand. There are four main groups used in practice.

PHOTOGRAMMETRICAL SURVEYS

Name	*Use*	*Scale*
Semi-graphical	Unmapped territory	1 : 50,000 to 1 : 25,000
Machine mapping	Development mapping	1 : 25,000 to 1 : 500
Close range	Urban areas	1 : 500 to 1 : 10
Macrophotogrammetry	Hydraulics Machine parts Accidents	1 : 10 to 8 : 1
Microphotogrammetry	Erosion, surface analysis	8 : 1 to 100 : 1

Camera. The basis of any photogrammetrical study is a negative or positive which is dimensionally as near perfect as possible so that reliable measurements may be made from it at any time.

The technique of measuring in this way depends on the fact that if the position of the cameras at the time of exposure are known with respect to any object on the negative, then the size and position of all other objects in the picture space may be determined. Accurate measurements are only possible by using a lens free from distortion, with its axis lying at right angles to the plate.

The design of the lens and camera to be used is basically important; in the case of lenses used in photogrammetry, testing usually concentrates on their resolving power, light distribution and distortion characteristics. Calibration of the position of the "principal point" and the "calibrated" focal length is required so that the most accurate value of the image angles on the object side of the lens may be obtained from image positions recorded on the photograph. The calibration data must remain constant over long periods, consequently the camera is normally rigid. The angular coverage of the lens is usually between 70° and 120°, the lenses used being of normal, wide-angle and super-wide-angle types, i.e. 300 mm. and 150 mm. or 100 mm. nominal focal length when covering a format size of 230 × 230 mm.

Photographic Material. For most aerial surveys film is used with a dimensionally stable base material, although for certain specialized purposes glass plates are occasionally employed. Glass diapositives are prepared from the film negative, and used in connexion with plotting machines for the preparation of maps. Paper prints may also be used for interpretation purposes and for less precise types of survey.

Methods. Although single photographs can be used, the more practical procedures normally require the plotting to be carried out from stereoscopic pairs of photographs. Binocular viewing, the stereoscope, or a similar binocular system, is used extensively for assessing and measuring the three dimensional models seen. The stereo-pair of photographs must satisfy, therefore, the conditions of binoc-

AERIAL PHOTOGRAPHY: Two views taken at a hyperstereogram apart from an aircraft provide a hyperstereogram, showing mountains and valleys in stereoscopic relief.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

STEREO PHOTOGRAPHIC SET-UP WITH SIGNIFICANT PARAMETERS. S, format side length. B, air base length between successive photographs. f, focal length of camera lens. H, flying height. L, length of ground covered by single photograph. LO, stereo overlap; this should be about 55 per cent of the dimension L. The base to height ratio B/H is important for measurements.

ular vision. In the cases of aerial photography the distance between the reference stations is such that the photographs overlap by at least 55 per cent in the fore and aft direction.

The separation of the perspective centres can therefore be expressed in the form of the base/height ratio $\frac{B}{H}$, where B is the base length (separation of the perspective centres) and H the mean flying height above the ground. In the case of wide-angle photography this ratio, given a 60 per cent overlap, is approximately 3 : 5.

The base to height ratio is of paramount importance, for the accuracy of the measurement of the third dimension depends a great deal upon the parallax measurements which have to be made.

The difference of parallax between selected points is measured, and the actual height of each point above ground level calculated.

Map Making. Today the majority of surveys used for map making are produced by means of photogrammetry, although a certain amount of ground control has to be carried out by the classical ground survey methods. If we take, for example, a pair of overlapping vertical photographs, in which the same area is covered over at least 50 per cent of each photograph, then the angle subtended by the air base will depend upon the distance of the ground point from the air base.

If, for this purpose, we call this angle the parallactic angle and measure its value in the plane containing the air base, we could calculate the distance of the point from some known datum level. It is not usual to measure this angle directly, but to use the image distance measured from the principal point on each photograph.

A stereoscope is frequently used to observe the pair of photographs. When the photographs are rotated until their base lines are colinear, a three dimensional effect is obtained if the separation of the photographs is satisfactory and when the bases are parallel to the eye base of the observer.

With a measuring instrument (which may be a parallax bar), the differing parallaxes can be measured.

With this, a normal procedure is to have a measuring mark for each photograph. Each measuring mark is brought over corresponding points of detail on the steroscopic pair of photographs. These marks are also fused stereoscopically. So when the exact locations of points are obtained, the fused "floating" mark appears to lie on the surface of the terrain at that point in the viewed model.

If the parallax bar is kept parallel to the base line, a measure of the linear parallax can be made at any point with reference to any other point shown on the photograph. This parallax difference is usually measured by a micrometer.

The simple methods outlined can be used on truly vertical photographs, but are subject to many errors if the photographs are tilted from the true vertical. Consequently these methods are not used a great deal and a number of complex plotting machines are employed in practice.

For terrestrial purposes, a phototheodolite is used. As the name implies, this is a combination of a theodolote and a camera. In this case, the two photographs forming the stereoscopic pair are taken at each end of a measured base.

Close Range Applications. Photogrammetric methods are also employed for non-topographic purposes, but they have not yet become as important as the mapping programmes used almost universally throughout the world.

Amongst these non-topographic uses, the following have received much attention: determination of volumes in open cast mines, architectural details, structural movements, medical research and industrial investigations.

PHOTOGRAMMETRIC HEIGHT MEASUREMENT. The image distance from the principal point in each photograph is measured in the direction of the stereo base. Then $(x_1 + x_2)/f = B/(H - \Delta h)$.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Furthermore, the photogrammetric techniques have been employed for making accurate records of traffic accidents.

Limitations. If the accuracy required of any particular investigation is known, a photogrammetric technique can usually be found which will satisfy the conditions. However, this technique might prove not to be the most beneficial on the score of economy or accuracy.

Undoubtedly, the widespread use of air survey methods for map making has been due to their speed and economy. Certain limitations previously paramount have now been considerably reduced by the introduction of better lenses, better cameras, and better film, whilst precision has been achieved by the use of very exact plotting machines.

Microphotogrammetry. In microphotogrammetry, two photographs are taken through the microscope in the normal way, the object being moved a definite distance between the exposures. The amount depends upon the scale of reproduction of the final positive. This produces a stereoscopic pair which enables the shape and dimensions of the object to be determined by parallax using floating dots. E.A.M. & G.T.S.

PHOTOGRAPHIC ALLIANCE OF GREAT BRITAIN. Founded in 1930 the Alliance acts as a co-ordinating body for the ten regional federations in Great Britain. By Membership of any Federation the individual clubs and societies, totalling over a thousand, are affiliated to The Photographic Alliance and receive certain services, benefits and privileges.

The Alliance publishes a Year Book in two parts. The Directory Section contains a list of all the affiliated societies, with particulars of meeting place, meeting night, name and address of secretary. The Syllabus Section details the various services provided for affiliated societies, i.e.: Lists of lecturers and lecture titles, lists of judges appointed for exhibitions and competitions; recorded lecture service; film-strip service; leaflet service; loan collections of prints and slides, etc.

An annual Inter-Federation Competition with trophies and awards in the various sections is organized by the Alliance. A selection of the prints and slides entered for these competitions is retained to form The Photographic Alliance Exhibition of British Photography which is shown at some six or seven centres in Great Britain each year.

Overseas Societies are also eligible for affiliation to the Alliance and a number of services have been instituted for the benefit of clubs and societies in many countries.

See also: *Clubs and associations.*

PHOTOGRAPHIC DEALERS' ASSOCIATION. Association, formed in 1914, as purely a retail organization with headquarters in London. Membership is confined to retail firms whose premises are suitable and who buy, sell and stock photographic apparatus and materials. There are members in all parts of the British Isles; the major proportion of their business is transacted with amateur photographers.

Association affairs are managed by its National Council of 16 elected members (representing areas of the British Isles) and 8 co-opted members, together with a limited number of Past Presidents. In addition, there are a number of standing committees which are concerned with particular aspects of the Association's work.

There are P.D.A. branches in a number of the larger provincial towns.

The P.D.A. policy is to encourage photographic knowledge and efficient service in those behind the retail counter. Considerable attention, therefore, is devoted to education. P.D.A. examinations, held annually, are open to all photographic dealers and assistants. The examinations are of two grades each including written, practical, and oral sections. The syllabus covers a wide range on the theory and practice of photography and the demonstration of all types of photographic apparatus.

The Association publishes a monthly journal, *The Photographic Retailer*, which is free to members. Also free to members and published in collaboration with the Focal Press is the *P.D.A. Reference Book*, with approximately 290 pages of technical, business and legal information.

PHOTOGRAPHIC SOCIETY OF AMERICA. Organization which was incorporated in 1937 as a direct development of the Associated Camera Clubs of America, first formed in 1919. It is a non-profit corporation which aims at "promoting the arts and sciences of photography and furthering public education therein". It is an international organization operating through committees, divisions, and chapters. The sole requirement for membership is a genuine interest in photography.

The Society is governed by its Board of Directors and the National Council consisting of the national officers, the Chairmen of the various Divisions, the District Representatives, the Chairmen of the Standing Committees, the immediate Past-President of the Society, and the Honorary Representatives when in the U.S.A.

The national officers, zone directors, district representatives, and division chairmen are elected by the membership, and the committee

chairmen are appointed with the approval of the Board of Directors.

Only the Executive Secretary and his assistants and the Editor and Advertising Manager of the *P.S.A. Journal* receive any remuneration.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The principal classes of society membership are Active, Sustaining, and Organizational. The Active group includes honorary and life membership. Sustaining membership includes business organizations who contribute to the financial support of the Society, and Organizational membership includes camera clubs, libraries, and educational organizations.

Facilities. The society maintains its headquarters in its own building in Philadelphia, where it also houses a permanent collection of outstanding photographs selected by the Committee.

The International Convention is held in a major city each year. Regional conventions are also held in various centres throughout the U.S.A. and Canada. Group and individual activities are conducted by committees with the assistance of district representatives and committeemen.

P.S.A. chapters (formal groups in immediate areas) present important photographic events and promote the use of photography for the benefit of the community—e.g., in the form of town meetings, shows, lectures and so on.

Two of the most important services to camera clubs and other groups are the National Lecture Programme and the Tape Recorded Lectures.

The Camera Club Committee is the chief channel through which P.S.A. serves groups. It makes available, in addition to its regular C.C. Bulletin of news and programme material, all the group services provided by the National Committees and the Divisions.

Other Activities. To provide for the various specialized photographic interests represented in P.S.A., the Society operates through divisions which function independently in their own particular interest under the constitution and bye-laws of the Society. Each has its own elected officers, its executive committee, its regular bulletin, and its own space in the *Journal* and is represented on the Board of Directors and the Committees. The Society dues include membership in any one division, and additional divisions may be joined at any time at a nominal annual fee.

There are separate divisions covering each of the following subjects: colour, journalism, motion pictures, nature, pictorial, stereo and techniques. In January 1955, the Amateur Cinema League of America voted to join the Photographic Society of America and merge with P.S.A.'s Motion Picture Division.

An autonomous Honours Committee awards Honorary Fellowships, Honorary Memberships, Fellowships, and Associateships. There are also Service Awards and Medals for extraordinary service to the Society and a number of special awards given through Society or Divisional Committees.

In addition to the Divisional and Committee Bulletin, P.S.A. publishes the monthly *P.S.A. Journal* and the quarterly *Photographic Science and Technique*.

The P.S.A. membership Directory is issued annually as a supplement to the *P.S.A. Journal*. It lists the full membership alphabetically and geographically. P.S.A. membership extends throughout the world.

PHOTOGRAPHY. Literally "writing with light" (from the Greek, phos, photos—light + suffix graphos—writing). The term is generally accepted as referring to any method of producing a visible image by the action of light—e.g., on light-sensitive silver salts, in the camera. The use of the term was suggested by Sir John Herschel to William Henry Fox Talbot in a letter dated 28th February, 1839. It was also used in the *Vossische Zeitung* of Berlin on 25th February, 1839, in an article over initials which point to the astronomer Johann von Maedler, who was a correspondent of Herschel's.

See also: *Photo.*

PHOTOGRAVURE. Printing process using a recessed image prepared by photo-engraving. The final printed picture derives its tone differences from the amount of printing ink deposited at any one point.

See: *Photomechanical reproduction.*

PHOTO JOURNALISM. The popularity of illustrated magazines and newspapers has created a highly specialized form of journalism in which the author works with a camera and thinks primarily in terms of pictures rather than of text. Hundreds of such examples of camera journalism appear in the press every week, and many of the leading weekly and monthly magazines in particular pay high rates for the illustrated stories they publish. Such stories may range from a series of consecutive shots of some novel subject to a fully documented account of the life and geography of some out of the way part of the world.

Requirements. Since the rewards may be very high indeed for outstanding work, and because few other fields present the same opportunities for travel, adventure and interesting day-to-day experiences, it is not surprising that so many photographers at some stage of their career try their hands at photo-journalism. But it is one of the most difficult branches of the profession, because it requires competence in two fields—photography and journalism—in addition to a high degree of personal organization.

The most common reason for the failure of so many photographers who are certainly good technicians is their ignorance of the rules for creating and maintaining interest; they tell the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

story exhaustively in every detail without emphasis or dramatization and the result is almost always boring.

The tyro, on his first assignment, usually produces pictures which are hackneyed, obvious and devoid of surprises, whereas the experienced camera journalist knows that the interest in his pictures often depends not so much on the raw material which confronts him, but on the way he handles it—on story treatment. He mentally plans the page layout as he selects and takes each picture. From experience he has a fair idea of how the editor will want to present the pictures. He knows that most editors look first for a key shot which can be featured—possibly as a full-page illustration—to establish the theme at a glance. Next they want subordinate shots with plenty of variety and contrast. So the old hand deliberately picks his scenes to make it easy for the layout man to arrange them to give the story continuity and development.

With the layout in mind the experienced worker deliberately varies his camera vantage point whenever possible. To establish locale and give the reader a bird's-eye view, he moves back and takes a panoramic shot. (If he cannot move back, he uses a wide-angle lens, to achieve the same effect.) To follow the development of the story, he may choose mainly medium shots, but he will alternate them with close-ups to illustrate or emphasize details. If it is impossible to move the camera close he uses a telephoto lens. This technique of dollying back and forward, or alternating lenses of varying focal lengths, is a standard device of the cine photographer, but it is equally effective for the still man who is working on magazine layouts.

Working Methods. Picture story assignments fall into two general classifications: those in which the photographer can record the events but not control them, e.g., prize fights, or trooping of the colours; and those where he can exercise his skill as a director, e.g., in shooting a rehearsal of a ballet company, or making a picture essay on the life of a country doctor.

Talents and abilities vary as much in this field as in any other; some photographers are good at fast moving events because they have fast reflexes, but they may not be equally successful in an assignment calling for stage-managing ability, or outstanding powers of diplomacy; others may be attracted to stories where they can shape the material. It is a rare man indeed who succeeds in every department. A good picture editor knows the capabilities of his staff photographers and freelances, and gives assignments to one or the other in accordance with their particular talents.

Camera journalism, like writing, has its own overworked and threadbare clichés. A stereotyped, worn-out idea is just as undesirable in an illustration as last year's catch phrase in an article. The old hand is suspicious of the obvious, easy-to-get pictures. He may take them as a matter of record—but for his real pictures he looks for something different. His problem, like the writer's, is often of finding a new way to tell an old story; for while a story may not be identical with one that has already been published, it may be just a repetition of a well-worn theme without a new twist to commend it. To give the theme a new look, the photographer must be inventive and ready to go a little deeper if he hopes to produce story angles which his predecessors have either overlooked or failed to exploit.

The beginner is usually so preoccupied with his technical problems that he is more worried about whether his pictures will be sharp than whether they will be interesting. The old hand does not have to think about his camera; perfect technique with him is automatic, and he is able to turn all his attention to handling his subject. His trained picture sense tells him immediately whether the existing situations will make interesting pictures; if they will not, he tackles the job of reshaping them. This may call for all his skill, personality and tact. Arranging the picture—and the people in it—is more often than not the thing that calls for the time and effort, while the actual camera work may require only a few minutes.

Some photographers object to staging and direction because they feel that it creates pictures that look forced and artificial. But if that is so it simply means that the photographer responsible does not know that part of the job. It takes real mastery to make contrived pictures look candid, and it cannot be done by merely telling people to relax and look natural. Anyone who thinks that people can be commanded to relax and look natural should try taking pictures with himself in front of the camera. He will then see how self-conscious the subject feels.

To get people to look natural in front of the camera lens the photographer must know how to make them stop worrying about themselves. This can be done by keeping their minds occupied with the business at hand. So the approach must be decisive; people are usually co-operative but they do like the photographer to know what he wants. He must be ready not only to explain, but to demonstrate if necessary. This means that he must be something of an actor himself.

Many camera journalists handle the literary as well as the photographic side of their assignments. Theoretically this should result in better integration of text and pictures—but in practice it creates problems. For one thing, it is difficult to establish one kind of relationship with people as a photographer and then set about establishing another kind as a writer. Also, taking photographs is a strenuous business which often exhausts people on both sides of the camera, and during a tiring photographic session no one is in the right mood for

discussion; interviews and flash bulbs do not go well together. Photographers who must do their own writing should take the pictures at one session and interview at another.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Rôle of the Caption. Many picture stories need only a hundred or so words of text because everything can be told in the pictures and their captions. In any case there are always captions to be written. It is a fairly safe rule that if the text has any plums, they should be transferred to the captions because there they are in a showcase and their enhanced impact gives a valuable lift to the pictures. This practice also helps to create editorial interest quickly, an important point when it is remembered that editors rarely have time to read the text on the spot and will hold the story only if pictures and captions look interesting.

The art of trenchant caption writing is brevity and condensation—plus research to make sure that every statement is correct and complete. Would-be clever captions that merely skim the surface and convey no real information are usually an admission that the writer does not really know his own story well enough, and should have spent more time looking up the facts. H.B.

PHOTOKINA. International photographic and cine exhibition and trade fair held usually bi-annually in Cologne, Germany. The first was in 1950.

PHOTO LETTERING. Method of producing display headings and lettering layouts for printing by using a photographic enlarger and a master negative of the required lettering characters. In this way headings can be set up in any required layout and the result checked before a printing plate is made.

See also: *Photo type-setting.*

PHOTOLITHOGRAPHY. Normal lithography using an image formed by photographic means instead of by hand drawing or transfer. It is a planographic process—i.e., the printing and non-printing surfaces are at the same level —in which the image is formed of ink-accepting areas and the background of ink-rejecting areas.

In one form of photolithography, the image is made by coating the surface of grained zinc or aluminium with bichromated albumen and exposing it under the photographic negative.

See also: *Photomechanical reproduction.*

PHOTO-LITHO MASTER. Photographically prepared plate from which copies can be taken by offset printing. The term is generally applied to plates made for office-copying processes. Normally, the master material, which can be aluminium, zinc, plastic, plasticized paper or translucent polyester, is sensitized and then exposed in contact with a negative or, in some processes, a positive.

Traditionally, plates are coated with a dichromated colloid on a mechanical whirler. Bichromated albumen is used for the negative process. Exposure hardens the colloid, and after exposure the plate is inked, then developed in water. This washes away the unhardened, i.e. unexposed, areas of the albumen leaving an ink-albumen image from which proofs can be taken. Bichromated gum is used for the positive process in which a negative image is developed on the master surface after exposure, and used as a stencil to produce a positive printing image.

Manufacturers now supply ready-coated plates which eliminate whirling and have good keeping qualities. The simple processing technique associated with these has found special favour in office copying. Prominent is the diazo pre-sensitized plate most usually in negative, but also in positive working form, where diazo compounds take the place of bichromates. Coating solutions which may be wiped on the plate, not whirled, are also available.

There are also many simple methods of master preparation based upon rapid office duplication systems. One such is the diffusion-transfer process using a silver halide material. A negative paper is exposed in contact with the original, then passed through a developer in contact with a master. Solvents in the master surface dissolve silver salts on the negative paper and these are transferred by diffusion on to the master. This is converted to a visible image and, after appropriate treatment, can be used for offset printing.

Transfer processes where dye or carbon is transfered are also used. With these, an exposed and developed sheet is brought into contact with a master on to which the image is transferred and used for printing. F.G.W.

See also: *Document copying; Photomechanical reproduction.*

PHOTOLYSIS. The photochemical reaction of light in decomposing a substance, characteristic of the most common reactions involved in photography.

PHOTOMATON. Proprietary name of automatic portrait camera for producing virtually instant pictures for passports and similar purposes. Usually built into portrait booths incorporating automatic lighting equipment and set up in railway stations, department stores and similar semi-public locations. The exposure cycle is initiated on insertion of the coin by the user, and yields one or more positives within about a minute. The working cycle includes automatic reversal processing of the prints.

PHOTOMECHANICAL REPRODUCTION

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Photomechanical reproduction, a distinct branch of photography, includes all photographic methods of preparing the surfaces used for printing reproductions of photographs, paintings and drawings in books and in the press. Where the photographer sets out to make a black-and-white or coloured print of his subject, the graphic arts craftsman has to produce a surface which, when treated with printers' ink and pressed into contact with a sheet of paper, will leave the required image behind. His problem is to transfer amounts of printing ink to paper in proportion to the depths of tone of the original picture.

Printing Surfaces. The printing surface must usually be metallic to be strong enough to withstand printing runs of many thousands at high speed. There are three types of printing surface:

(1) The areas which transmit the ink may be raised above the general surface of the metal as in an ordinary metal type character or hand-cut wood block. This is known as cameo (raised), letterpress or typographic printing.

(2) It is possible to print from a perfectly flat surface if parts of it can be made to have an affinity for printing ink while the remainder of the surface repels it. Such processes are known as planographic (printing from a plane) and the most usual method is lithography.

(3) An image may be cut or etched into a flat surface which may then be flooded with ink, the surface wiped or scraped clean, and ink remaining in the incised hollows transferred to paper. Here the image may be recessed into the metal more or less deeply according to the depth of tone of the picture. This principle is called intaglio (meaning "incised" and pronounced "intahlio"). Photogravure is the only photo-engraved intaglio method, although there are many non-photographic techniques such as etching, drypoint and mezzotint which use the principle.

Tone. Only the last of the three basic methods is capable of depositing printing ink in different densities on paper. A photogravure image, for instance, has the quality of a continuous tone picture in which the tones vary in density from point to point as in a bromide print.

The typographic and planographic processes deposit printing ink upon paper at full strength, or not at all—that is, the tone is discontinuous. In these processes the appearance of intermediate tones is brought about by means of an optical illusion. The effect of varying densities is produced by a regular pattern of dots which are small in the light tones and larger in the darker tones. The dots are so small and numerous that the eye sees only the general effect and does not see them separately.

THE PRINTED IMAGE. Differences in printing processes show up under a magnifying glass. **Left:** *Letterpress image. Squeezing of ink towards edges of dots and lines produces characteristic ink squash effect. Irregular shaped dots are due to slight differences in image detail.* **Centre:** *Lithographic image. There is no ink squash or any sign of an impression mark on the paper, as would be obtained with letterpress printing. The ink deposit is very even; the half-tone dot shape is similar to the letterpress dots.* **Right:** *Photogravure image. Half-tone dots are more or less of the same size, but differ widely in density owing to varying ink deposits. Line images also need a screen pattern to provide a bearing surface for the doctor blade after inking.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MACHINE PRINTING. Top: *Typography (e.g., letterpress). The printing image is raised and covered with ink by the inking roller, before printing on the paper.* Centre: *Planography (e.g., lithography). The printing image is on the same level as the non-printing surface and is damped before inking.* Bottom: *Intaglio printing (e.g., photogravure). The printing image is etched into the non-printing surface, and filled with ink. A doctor blade cleans off the non-printing surface. In all cases:* A, *platen;* B, *paper;* C, *ink;* D, *inking roller (preceding paper across printing surface in direction of arrow);* E, *printing plate;* F, *machine bed;* G, *damping roller;* H, *doctor blade.*

LETTERPRESS LINE BLOCKS

A line subject is a drawing in black lines on a white background which, for printing purposes, has to be duplicated, line for line, exactly as the original. The copy negative may be enlarged, reduced, or the same size as the original.

Making the Negative. The engraver first makes a photographic negative in which the black lines of the drawing are represented by transparent areas and the white background by dense areas, as nearly opaque as possible. The wet collodion process (invented by Scott Archer in 1851) was commonly used until around 1950. Since the invention of "lith" dry plate emulsions soon after World War II, nearly all photographic work in graphic arts has been done on dry plates and, to an increasing extent, on film. Stripping film and negative paper are also used for ordinary line work.

The process line negative must be laterally reversed, that is, the lettering must be right way round so that when the resulting printing block is inked and pressed on paper the proof will be the right way round. The negative image is reversed by reflection from a mirror placed at 45° in front of the lens. Generally the mirror is a solid glass prism with its long side silvered for convenience and permanence.

Printing on Metal. The powderless etching technique, invented in America in the early 1950s, is rapidly replacing the older methods of making line plates.

For conventional line block-making, a zinc plate about $\frac{1}{16}$ in. thick is coated with a solution of dichromated (and hence light-sensitive) albumen. The metal is spun rapidly in its own plane over a hot plate. This centrifuges off the surplus solution and dries the coating.

The plate is then exposed in close contact with the negative to the light of an arc lamp.

The unexposed dichromated albumen coating is soluble in cold water, but where light has fallen it becomes insoluble. After exposure, the coating is inked very thinly and the plate is put into a bath of water and lightly rubbed with cotton wool. The soluble albumen dissolves away leaving a visible image in the form of light-hardened albumen with a coating of ink. The plate is dried, its image dusted with finely powdered bitumen and finally warmed until the bitumen fuses into an acid resisting layer.

Line Etching. The metal between the lines of the image must next be etched away with nitric acid until it is below printing depth. As the acid begins to etch down between the lines it also tends to etch sideways. This action would very soon eat away the finer detail so the sides of the lines must be protected.

After a very slight etch the plate is treated with a weak gum arabic solution which provides a moist, ink repelling layer over the bare metal. It is then rolled-up with a greasy ink which is accepted by the bitumen image but not by the damp bare metal. The plate is then dried and dusted with a special acid-resisting red resin powder called dragon's blood. This has the property of liquefying into a viscous mass which does not run when it is heated. Upon cooling, it provides an efficient acid resist. The dragon's blood is usually applied and "warmed-in" four successive times between each etch, being brushed across the plate in four opposing directions. In this way the powder piles up against the sides of the lines like a snowdrift, providing an efficient protection against the sideways etch of the acid.

This process of alternately protecting the sides of the lines and etching further is continued until the plate is etched to sufficient depth. The ink and dragon's blood is then washed off, and a layer of hard ink is rolled upon the top of the lines. The plate is treated with a weak etching solution which removes any roughness at the sides of the lines, leaving

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

them with a sturdy pyramidal cross section.

Finally, the plate is cleaned, blackened with a solution of copper sulphate, and the top polished with charcoal.

Mounting. It is possible to etch away all the metal not required to be at type height, but in practice this would waste time and materials, and so all large clear areas are covered with resist before etching and are afterwards cut away on a routing machine before the plate is mounted.

A router is a vertical milling machine with a cutting head that revolves at about 20,000 revolutions per minute. An open line block consists of little more than a skeleton of metal pinned to the wooden base at any convenient points within the work. The finished thin printing plate is mounted to type height (0·9186 inch) usually upon well seasoned oak or mahogany or on synthetic resin-bound chipboard. Plates are frequently mounted on metal bases for use on modern high precision presses.

HALF-TONE BLOCKS

Half-tone blocks can be regarded as line blocks in which the image is made of dense black dots. The illusion of shading or half-tones is caused by variations in the sizes of the dots, not by any difference in the density of the ink deposit. The original photograph is copied on a process camera as for line work with a reversing prism on the lens. In this case, however, a normal copy negative is unsuitable because the image from which the block is etched must consist either of acid resist or clean metal.

The Process Screen. When the photograph or any other type of picture is copied for half-tone reproduction, the image is broken up into a dot formation by a screen placed at a short distance in front of the plate or film in the process camera. The screen consists of two sheets of glass, each ruled with opaque lines equal in width to the spaces between them, and sealed together, face to face, with the sets of lines at right angles to each other and at 45° to the base.

The distance of the screen from the plate is adjusted so that the light passing through each aperture in the screen forms points of full illumination behind the centre of each screen aperture. Around these brilliant points, the intensity of the light falls off until it reaches a very low level behind each line.

If there were plain white paper in front of the lens, a short exposure would produce a pattern of very small dots on the photographic plate corresponding to the central points of full intensity light. These dots would be larger for longer exposures and eventually, with sufficient exposure, they would join together.

When the photo-engraver makes a negative for half-tone reproduction, he adjusts the size of the lens aperture and the distance of the screen from the plate with respect to the number of lines per inch of the screen and the distance from lens to image, so that light tones of the original picture are represented, in the half-tone negative, by large square opaque dots just joined at their corners, and dark tones by very small dots.

Contact Screens. During the past decade there has been a considerable increase in the use of the vignetted contact screen. This consists of a thin sheet of film containing an image of vignetted dots, formed either in a magenta-coloured grainless dye, or in extremely fine grain neutral-coloured developed photographic silver. It is used instead of an engraved cross-line screen, and is held in vacuum contact upon a sheet of lith film in the camera, or for contact printing.

For direct colour separation work the neutral grey contact screens are used. For monochrome work, or for recording colour-separated continuous-tone negatives or positives in half-tone, the magenta screens are claimed to have advantages. With the grey contact screen, the contrast of the half-tone result can be controlled only by adjusting the quantity of "flash" exposure, which is a short overall general exposure affecting only the smallest dots. All other tones form larger dots which completely cover the "flash" dot. The magenta contact screen has three advantages. Firstly, the screen image is completely grainless, and therefore forms thoroughly sharp and clean dots. Secondly, the controlled flash technique to control contrast can be used as with grey screens. Thirdly, the magenta screen yields images of varying contrast according to the colour of the light used for the exposure.

Some manufacturers of grey contact screens claim that they may be used for making both negatives and positives in half-tone. Others consider that the dot formation of the screens should be different for each purpose.

The contrast range of the screen dots can be varied to obtain more, or less, contrast at the top, the bottom, or in the centre of the tone range more effectively than with ruled screens, and this is a most valuable technical advance. In addition, it is almost impossible to obtain a faulty dot structure in a properly exposed contact screen half-tone, as often happened with a ruled screen. Thus the work of the camera operator is considerably eased.

The Photographic Materials. Since the last war the wetplate process has been almost entirely discarded, dryplate emulsions being used almost exclusively, with a rapidly increasing trend towards the use of film, even for colour separation work, now that dimensionally stable film base materials (polyester, etc.) are available. Some monochrome work is done on "ordinary" (blue-sensitive, "colour-blind") emulsions, but "lith" material which is orthochromatic (or panchromatic) and gives extremely dense lines of exceptionally fine grain, or dots in a completely clear ground, is very popular.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Metal Printing. Half-tone negatives are printed on metal about $\frac{1}{16}$ in. thick. Copper is often used for screen rulings finer than about a hundred lines per inch, and zinc for coarser rulings. The metal is coated with a cold-water-soluble fish glue solution containing ammonium dichromate. This coating is dried and then exposed under the negative to arc light in a vacuum pressure printing frame. The glue that is exposed to the light that shines through the clear parts of the negative becomes insoluble in water, but where it is protected by the opaque dots that form the negative image it remains soluble. So, when the metal is washed under a stream of water, the soluble glue dissolves away and leaves a positive of the image in the form of an insoluble glue coating.

In this condition it is difficult to see the image, so it is dyed in a solution of methyl violet. Then, if the appearance of the image is satisfactory, the glue is "burned-in" to an acid resisting carbon enamel by heating the metal very strongly over a gas flame.

Half-tone Etching. Dilute nitric acid is used for etching zinc, and a solution of ferric chloride (iron perchloride) for copper. While the principle of etching is the same for both metals, the technique varies; for instance, copper can be suspended horizontally in an undisturbed solution of ferric chloride (a "still bath") and, as no gases are evolved by the reaction, the plate etches satisfactorily. This method would be useless for zinc because gas is given off during the zinc etching process.

Copper can be etched electrolytically (by the reverse of electro deposition) but the method has never been successful with zinc, although claims have been made for a zinc etching electrolytic machine. Etching of either metal may be carried out either by machines which throw the etching mordant against the plate, or in mechanically rocked baths which keep the solution constantly agitated.

The "underbiting" effect, which has to be prevented in line etching, is allowed for in half-tone etching and is even put to very good use. Before the image is etched, the lightest tones of the picture consist of large squares of resist almost joining at the corners, and the darkest tones consist of a continuous expanse of resist pitted by minute holes. The range of tone gradation is represented by the range of variations between those two extremes.

During etching, the mordant bites sideways as well as downwards, undermining the dots and, as the enamel is brittle and because the effect is helped by brushing, the sides of the dots break off and they become progressively smaller in the light tones. At the same time, the minute pits in the dark tones become enlarged; so that all the tones of the picture become lighter until a stage is reached when the dots representing the lightest tone become so small that they cannot be etched any further without being lost altogether.

Fine Etching. The tones of the final reproduction can be controlled by etching certain selected areas of the block while others are held back by a protective coating. This process is known as fine etching. After a suitable amount of rough etch, sufficient to provide printing depth, the darker tones are painted-in with an acid-resisting ink and the remainder of the image is allowed to lighten during the next etch; then further tones at the lower end of the scale are painted-in and the remainder lightened still further until perhaps all of the picture is covered with resist except for highlights. In a landscape, for instance, light clouds would be lightened in tone just enough to lift them away from the main sky, after which all the "stopping-out" paint is washed off and the plate is ready for mounting.

A certain amount of fine etching is generally necessary to improve the quality of the reproduction, especially when making a block from an over-contrasty bromide print. Photo-engravers can readily increase the contrast of a slightly flat print, but far more often they have to fine-etch for highlight detail or for shadow-detail because the prints are too contrasty and lacking in gradation.

Fine etching is also necessary because of the wide variation possible in printing conditions. The type of ink and paper to be used, whether the plate is to be duplicated, the type of machine and the printing speed, and the actual printing technique all radically affect the type of block that is required.

In colour work the tones of many colours in the different printings have to be altered by fine etching to allow for the faults in printing inks.

Powderless Etching. Since the early 1950s the powderless etching technique, originally used for etching line plates, is used widely throughout the photo-engraving industry. Invented by the Dow Chemical Corporation of America and used for etching magnesium, it has since been adapted also for zinc and copper.

The etching mordant solution (nitric acid for magnesium, or zinc and ferric chloride for copper), contains also an oily substance and a wetting agent, the acid solution and the oily substance being pumped mechanically through the machine and mixed into a semi-emulsion. The mixture of solutions is either splashed by means of paddles or sprayed against the plate to be etched. The oily substance tends to separate out and to be deposited against the sides of the lines or dots of the image, where it resists the action of the acid and automatically builds up a protection at the sides of the image. Thus line or half-tone plates (or indeed, a combination of line and half-tone) can be etched in the machine in one operation.

Obviously this method does not permit tone correction by fine etching half-tone plates, so the correction has to be introduced at the earlier negative stage.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Mounting. The finished plates are mounted to type height in much the same manner as for line work. An ordinary squared up plate is simply bevelled around all four sides and tacked upon the wooden mount with small nails through the bevels. To allow for a caption close to the base of the picture the plate is often trimmed flush at the bottom edge and it can, if necessary, be trimmed on all sides. F.H.S.

Rotary Printing. The traditional method of printing for high quality work is from flat plates or formes containing both types matter and illustrations. For newspaper and other bulk work, this method is too slow and printing cylinders rotating at a high speed are used. Since ordinary metal blocks cannot be bent to fit the curve of a cylinder, curved plates are prepared from the flat blocks via paper or plastic moulds. These are formed by pressing against the flat printing area, they are then bent to the required curvature and the metal (usually a lead-tin alloy) cast into this shape. The resulting curved plates can then be mounted directly on the printing cyclinder.

Electronically engraved blocks and also plastic plates can be made in such a way that they can curve directly round the printing cylinder.

Electronic Engraving. Half-tone blocks are nowadays also made by electronic engravers which bypass the whole process of preparing half-tone screen negatives, printing down on metal, etching, etc. The procedure is briefly as follows.

A fine beam of light in conjunction with a photo cell scans the photograph to be reproduced. That is, the cell and beam move across the picture in successive lines, rather like the lines of a television screen image. At each point the photo cell registers the amount of light reflected by the surface of the picture. A light tone reflects more light than a dark tone.

The current from the photo cell is fed—via appropriate amplifying circuits—to an engraving machine and controls a stylus. This travels across a metal plate in synchronism with the scanning movement of the light beam and photo cell on the picture. The stronger the current from the photo cell, the deeper the stylus digs into the metal while engraving. The stylus is cone-shaped, so that the deeper it digs into the plate, the less plate surface there is left between each scanning line and the neighbouring one.

The final half-tone image may thus be built up of regularly spaced lines of varying thickness. The darker the tone, the broader the lines left standing up on the metal plate; the lighter the tone, the narrower the lines, and hence less ink is transferred by the plate on to the paper.

In the more modern electronic engraving machines the stylus is driven into the engraving material intermittently at the rate of several hundred times per second. This forms image dots similar to the dots of a normal half-tone block prepared photographically, but with a more regular structure.

Electronic engraving permits no etching, but has the advantage of being very quick. A line block can be made in as little as 10–15 minutes. The process is also largely automatic. A considerable measure of tone control and correction is possible by adjustments of the circuit which controls the engraving stylus. It is even possible to engrave a positive block from a negative by reversing the impulses electronically. Also, the transmission from the scanning spot movement to the stylus movement is electric, and can be adjusted to yield blocks of any enlargement or reduction as compared with the original.

Electronically engraved blocks are frequently used in newspaper printing, where the speed is a real asset and fine correction is less important. The electronic engraver can yield both flat printing plates and curves plates for high speed rotary printing.

Plastic Plates. A comparatively recent development is the use of photo-sensitive plastics in photo-engraving. The printing plate is here a layer of plastic coated on a stiff or flexible (according to requirement) metal backing. This is exposed in contact with the line or half-tone screen negative to ultra-violet radiation. The exposure polymerizes the plastic and renders it insoluble; the unexposed areas are then washed away in a suitable solvent, leaving the printing surface in relief. Plastic polymer printing plates are quick to make (the entire operation takes about 15 to 20 minutes). As no etching is involved, the half-tone negatives must be somewhat different in character from those used for conventional blocks. L.A.M.

LITHOGRAPHY

Lithography is the most common planographic printing process. It was discovered and perfected in its entirety by one man, Alois Senefelder of Solnhofen, in Bavaria in 1796. The principle on which it depends is that of the mutual antipathy of grease and water. Senefelder found that if a greasy image is formed on an absorbent limestone which is subsequently damped with water, then the image will "take" a greasy ink and the damp areas will refuse to accept the ink, so that proofs can be taken from the stone.

Senefelder's process has been modified in many minor ways—e.g., by the use of thin grained metal sheets instead of the stone; the production of the image by photographic means, and printing by first laying the image on a stretched "blanket" of rubber and then "offsetting" it to paper. But the basic principles remain unaltered.

For over a hundred years lithographers printed from stones, and their presses had to be enormously strong and heavy to exert the necessary printing pressure. In consequence it was impossible to attain high speeds or to print on very rough paper.

At the beginning of this century—about 1909—a new method of printing came into use. In this method, the printing surface consists of a thin zinc or aluminium plate clamped tightly around a cylinder on the printing machine. As the plate cylinder rotates, the image is first damped and then inked. It then rolls into contact with a rubber-faced "blanket" and the ink image transfers itself on to the rubber surface. This then rolls into contact with the paper and prints the image upon it. The image is said to be "offset" on to the paper and the process is known as "offset" lithography.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Offset machines can be run at high speed and will print satisfactorily even on very rough paper. Colours can be printed in rapid succession by this process.

Photo-litho. To reproduce a continuous-tone image by lithography, it is again broken up into a half-tone image with the aid of a half-tone screen. For photo-litho work contact screens are more popular than the ruled kind, and all contrast and tone control has to take place at the time of the exposure since no etching or fine etching is possible.

The screen negatives are printed on to the grained and coated metal plate. The coating is a dichromated colloid which hardens and becomes insoluble on exposure, while the unexposed portions dissolve away on subsequent treatment. The hardened colloid then is water repellent but accepts greasy ink after the whole plate is dampened.

There are also a number of other processes for preparing photo-litho plates from half-tone or from line originals. An offset photo-litho process is also used for a variety of office copying systems, especially when large numbers of copies are required from one original.

Certain photo-litho plates form a positive image from a positive, and hence require a screen positive as the starting point.

Conversion of Letterpress Blocks. Sometimes an image from a letterpress block, or even type-set matter, has to be used for photo-litho processes. One way is to photograph a printed proof, and use that for preparing a litho plate. It is a roundabout way, and not really practical for half-tone illustrations since the sharpness of the half-tone dot inevitably gets lost on re-photographing.

Various methods have been proposed for photographing direct from metal blocks or metal type. One of the most recent processes uses a pressure-sensitive instead of a light-sensitive film. This is placed in contact with the block or type matter, and bombarded in a special machine with small steel balls. The treatment accurately reproduces the raised letterpress image—including every dot in a half-tone image—on this conversion film, which after suitable treatment yields a dark coloured line or half-tone image. This can then be used directly for printing on to sensitized zinc or aluminium plates to produce litho plates.

PHOTOGRAVURE

Photogravure is a photo-engraved intaglio process. Modern screen rotary photogravure dates from its invention by Carl Klič in 1895, although Fox Talbot's photoglyphic engraving process of 1852 was an intaglio method somewhat akin to photogravure.

By this method the image does not depend upon optical illusion for the effect of tones of the picture as do the letterpress and lithographic processes. In photogravure the image is etched into the surface of the printing cylinder; deeply in the areas representing the dark tones and less deeply in the lighter tones. The image is printed by flooding the cylinder with ink, scraping it off to surface level with a long steel doctor blade and transferring the ink from the etched hollows to the paper.

Printing plates or cylinders for this type of reproduction are given a screen pattern consisting of lines at right angles at surface level to provide a continuous support for the doctor blade. The lines are less than one third of the width of the spaces and of the order of 175 per linear inch, so they are too fine to be seen with the naked eye. The image is etched to its continuously varying depths (according to the tones of the picture) in the minute square pits between the lines.

Partly because of the high printing speed, and also because of the liquid nature of the ink, the screen lines are more or less obscured in the dark tones so that beautifully intense blacks can be obtained and there is a limpid clarity in the lighter tones which cannot be obtained by any other process because of the intrinsic difference between continuous and discontinuous tone.

The Negative. For line work and type a line negative is made of the same kind as for letterpress blocks or photolithographic plates, that is, as opaque as possible in the area representing white paper and transparent in the areas representing the black lines. A positive has to be made from the negative and, if it is to be made by contact printing, then the negative is prism reversed as for letterpress work.

For tone illustrations such as photographs or wash drawings the negative is an ordinary continuous tone copy negative.

The Positive. The image used for preparing the etching resist for the printing cylinder must be a positive transparency. The positives of the illustrations and of the text must lie within specified density ranges because they are planned in page formation and printed as one.

The Resist. The etching resist consists of a negative image of light-hardened gelatin in which the areas representing dark tones of the picture are very thin and the thicknesses increase in proportion to the tones of the subject, the thickest area representing the lightest tone.

Carbon tissue—paper coated with pig-

mented gelatin and similar to that used for carbro printing—is used for the resist. It is rendered light-sensitive by bathing it in a solution of potassium dichromate and then drying in darkness. The sensitized tissue is first exposed to arc light in a vacuum pressure printing frame behind the photogravure screen, and then the screened tissue is exposed to the arc lamp behind the combined positive of the text and illustrations.

The tissue is transferred to a copper cylinder and "developed" in a stream of warm water which washes away the soluble gelatin and leaves only the light-hardened gelatin in the form of an image of varying thickness. The finished "print" is then dried.

Instead of carbon tissue, special photographic films can also be used. After exposure, development hardens the emulsion image-wise. This emulsion is then stripped off the film base and transferred to the copper cylinder, followed by warm water development, etc., as with tissue. Gravure films of this kind have the advantage of being more consistent in their properties, while the visible silver image also makes judging of image density easier.

Etching the Cylinder. The image is etched into the surface of the copper with a solution of ferric chloride (iron perchloride). The result is a surface in which the depth of the etched areas varies according to the tones of the original image. The tone range of the etched image is controlled by suitable variations in the strength of the etching bath. Etching is started with a strong solution.

The particular tone which is to be "brought in" and etched is controlled by the strength of the solution, and the depth of the etching is controlled by the time for which the etching is allowed to continue before the next weaker bath is employed; in that way the tone range of the result can be governed to a surprising degree,

but there are definite limitations and any further adjustments have to be taken care of by retouching the original negatives and positives before the carbon printing is done.

The line work and text matter on the cylinder are sometimes etched separately from the illustrations and only two strengths of ferric chloride are used; a slightly weak one to make sure that etching starts on all the work, and a stronger one to continue the etching and to ensure that there is no penetration in the "whites" surrounding the work.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

COLOUR

All the standard photomechanical reproduction processes may be adapted to the reproduction of coloured originals.

Principle. It is obvious that if one can print from a letterpress block, a photo-litho plate, or a gravure cylinder upon paper, in black ink, then there is nothing to prevent one from using ink of any colour instead; further, there is nothing to prevent one from printing again in another colour, from another printing surface, in register on the first proof, and so on as many times as required.

So, by taking a set of three-colour separation negatives of any coloured scene, photo-engraving a printing surface from each, and printing them in their appropriate colours in register upon white paper, the result will be a colour print. This is the broad principle of all colour photo-engraving.

Practical Difficulties. The main difficulty is the impossibility of making printing inks which each completely absorb one third of the spectrum of white light while perfectly reflecting the other two-thirds. By reason of the inefficiencies of the printing colours alone, blues, purples, greens and mixed colours such as browns and olive greens are bound to be degraded to some slight extent.

This is one of the two main reasons why colour masking and/or hand correction are necessary in graphic reproduction. The second reason is that the reproduction curve of any of the graphic arts reproduction processes is never a straight line at the top and bottom ends of the scale, even for monochrome reproduction, so it is also necessary to contrive the "tone correction" in one way or another.

Colour and tone correction are usually introduced together, either by "automatic" photographic masking techniques, or by hand correction, often today principally by masking, and the remainder by hand work. For letterpress block making, the hand correction is usually introduced by the colour etcher when the plates are etched. For photo-lithography the initial continuous tone colour separation negatives can be corrected, usually by dye retouching, principally for the light tones (the dense areas of the negatives), and then by "dot-etching" the half-tone positives by ferricyanide-hypo reducing the size of the dots which form the image. For Photogravure both the negatives and the positives are in continuous tone, so the negatives are dye retouched, mainly for the light tones, in much the same way as for litho and then the positives, made from them, are also dye retouched for the dark tones (dense areas) of the picture.

Colour Masking. The "automatic" photographic method of colour correction, and often tone correction also, is based upon the general principle of interposing a weak positive, made via one of the colour filters, into the light path when printing an image from a colour separation negative made with another colour filter. Obviously the interposed positive is bound to modify the separation negative selectively, because of the different response of the different colour filters, and if the filters are wisely chosen, then the combined effect can be advantageous. Conversely, it is possible to modify the colour separation from a positive by interposing a weak negative mask made with a different colour filter.

For example, the magenta-red printer (green filter separation) negative from a positive colour transparency is never dense enough in the blue and green colour areas. So, without hand or photographic colour correction, it always prints too much red on the blue colours of the reproduction, degrading them to a purplish colour. It also prints some red on green colours, where it should print none, thus degrading them to brownish tones.

But a red filter negative is, of course, dense in red, orange and yellow colours, and transparent in the areas representing blues and greens (it is a cyan blue-green printer). That negative, at about half strength, may be used as a mask and bound up in register with the colour transparency, the combination being photographed with a tri-colour green filter. Then, because of the mask, more exposure must be given to sufficiently affect the areas representing yellow and orange. As the mask is transparent in the blue and green areas, they are recorded more dense than they would otherwise be in the resulting magenta-red printer colour separation negative which is thus "automatically" colour corrected.

This simple form of colour masking may also introduce considerable improvement in the rendering of the darker tones of the transparency. An earlier highlight mask may have helped at the other end of the tone scale. Many colour positive transparencies have a too great contrast range for direct graphic reproduction, but an incidental effect of the negative colour mask is to reduce the overall contrast of the transparency and mask combination to bring the range within the scope of the reproduction process. If the mask is exposed and developed so that only the light end of the tone range is recorded, then the contrast reduction is limited to that end. When the combination is colour

separated, the total tone range is shared between the whole of it, thus the tone range is comparatively extended.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Colour Proofs. For all methods of graphic arts colour reproduction it is necessary to take colour proofs so that the progress of the work may be gauged. Many highly skilled craftsmen gain an astonishing intuitive grasp of colour combination quality and they often need to make remarkably slight adjustments to achieve the required results. But that can only be demonstrated by the progressive proofs before the expensive stage of the machine printing.

Progressive proofs are a set of prints from each of the three or four separation printing plates (or cylinders), each in their respective colours and in their combinations. The yellow plate is commonly also printed separately in a darker colour so that its quality can more readily be seen. The proofs not only show that the reproduction work is efficient, but they also provide a valuable guide to the machine printer as to the weight of colour that he needs to obtain in each printing. For this reason the proofs should be on the same paper and in the same inks as will be used for machining, and preferably printed in as nearly as possible the same manner.

The photogravure process is the only one of the three which prints effectively in continuous tone. The image of a tone subject has to be recorded in half-tone dot formation for printing by letterpress or litho, which introduces another problem in colour reproduction. If one lays comparatively even layers of coloured ink at varying intensities, as in a modern integral tri-pack colour print or a photogravure proof, then the colour combinations are different from the effect obtained by printing various sized dots of the full weight of the colour by the half-tone method. Further, the half-tone colour effect changes according to the position in the tone range because the dots representing tones darker than a mid-tint are likely to fall upon one another, while the dots representing lighter tones are more likely to fall beside one another. This distinctly alters the hue and has also to be allowed for by colour etchers and retouchers.

Screen Angle. The three or four printings of a colour reproduction must not have the dot formations all at the same angle because it is not possible to print with the dots in precise coincidence. If the fit is not exact, the dots fall in and out of "phase" and produce a large blotchy effect (Moiré pattern) which ruins the result. So the screen angle of each printing is set as widely different as possible.

The yellow printing reflects so much light that it is the least likely to "pattern", so it is usually set at the horizontal and vertical position. The magenta-red printing is at 15° the cyan blue-green at 75° and the black 60° farther, at 135° (which is effectively the same as 45°). Thus the three strongest colours are as widely separated in screen angle as possible and the yellow printing lies between the blue and black. For three colour work the blue, being the darkest colour is at 45°, the yellow taking the 75° angle, and the red remaining at 15°.

When more than four colours are used, as for example, in some photo-lithography, then the pink is often run on the red angle and the light blue on the blue angle. Some printers prefer to reverse that order, but one always runs a light colour on a dark colour angle and never two dark colours on the same angle.

The Black Printer. Theoretically it should be possible to reproduce a colour subject in only three printings, but four are generally used for two main reasons. The first is that the accompanying text is usually printed in black, so it is not difficult to include a black printing on the illustrations if there is any advantage.

Secondly it is very difficult indeed to print each of a three colour working with such exact colour balance that the result is perfect. But if the neutral tones and dark colours are produced with the help of a black printing, then some slight lack of balance in the colour printings will be masked and a thoroughly acceptable result is much more readily obtained.

Finally, in the case of "wet-on-wet" printing, where the colours succeed one another on the machine before they have a chance to dry, it is important that no two colours shall overprint at full weight. So the heavy tones must be built up with the help of the black printing.

Electronic Correction and Engraving. Electronic aids are frequently used nowadays to ensure correct balance and effective masking of separation negatives intended for photo-mechanical printing. This correction is introduced at a stage of making positives from a separation negative, and these are then used for producing the screen negatives which lead to the blocks.

Briefly, electronic correction consists of analyzing the three separations simultaneously by scanning them with a flying spot light source and measuring the light intensities coming through the three separation negatives with photo cells. The output of the latter for all three negatives is fed into a unit which controls a further flying spot source which prints each of the separation negatives in turn to a positive. The electronic correction automatically over- or under-exposes areas of the separation negatives corresponding to specific colours, and so introduces the mask effect during a single printing stage. Equipment for this purpose is necessarily complex and expensive.

Three- and four-colour printing blocks can also be produced by electronic engravers which scan a colour transparency (or a colour print) in much the same way as an electronic engraver for a black-and-white picture. Only in this case the colour picture is scanned three (or four) times in succession through the appropriate separation filters. Colour and tone corrections can again be introduced by suitable adjustments of the electrical circuits involved.

OTHER METHODS

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

During the century since photo-mechanical reproduction came into use, many different processes have been invented; some, like the Woodburytype, were superseded because of economic pressure, others such as collotype have remained in use for special purposes. The few which had thoroughly distinctive features are outlined below.

Typographic Processes. Here the field for originality is limited by the fact that one can only have a raised printing surface and a recessed non-printing surface.

The regular "half-tone" screen dot formation has been varied in many ways for different processes.

(1) By changing the shape of the dots, as with the Schultze screen which makes them rhomboid instead of rectangular.

(2) By changing the size, as with a special Max Levy screen which produces extremely fine dots that coalesce into larger ones in the darker tones.

(3) By changing the pattern as in the Metzograph screen and many others in which the pattern was either broken up or based on straight or wavy lines.

Planographic Processes. There have been more variations on the planographic processes than on any of the other methods. Apart from various offset printing techniques such as litho-deep, dot-etching, bi-metallic plates and photo-composing (which also applies to photogravure), all of which have been assimilated into the parent process, there have also been two complete processes which were radically different: Collotype and Pantone.

Intaglio Processes. The principal variations of this basic reproduction principle are the Bitumen Grain Process, Invert Half Tone and Woodburytype. F.H.S.

PHOTOMETER. Instrument for measuring illumination, often used to determine the brightness of a light source. The type of instrument usually called a photometer is strictly a comparison photometer in which the brilliance of a given light is assessed by comparing it with a standard light.

The Bunsen or grease-spot photometer is the simplest type in general use. This consists of a sheet of opaque white material with a central translucent spot or ring formed on it with oil or melted grease. When the spot is illuminated from the front, it looks darker than the surrounding material; when it is illuminated from the back it looks brighter; when the illumination on the front and back is exactly equal, it disappears.

Measurements are made by fixing the standard source at a standard distance from the spot, and adjusting the distance of the other source until the spot disappears. The relative brightness is calculated according to the inverse square law.

Camera Exposures. Until recently photometers were not regularly used in the photographic field although they have been widely used by illuminating engineers. They are also used in photography for measuring subject brightness, i.e., as exposure meters. In one such instrument a telescope is used to sight the scene and a very small mirror occupying about one-quarter degree in the middle of the field is illuminated by a lamp. This lamp is fed from a dry battery which is incorporated in the base of the instrument, and a series resistance is inserted in the circuit of the lamp so that its brightness can be varied. A photo-electric meter, consisting of the usual photocell and micro-ammeter is used to adjust the brightness of the lamp to a standard value, after which it can be used for measuring the brightness of the scene. A pair of neutral density wedges is arranged between the lamp and the illuminated mirror. Adjustment of these wedges to obtain a match actuates a calculator from which the exposure can be read.

Alternatively, the resistance setting required may be taken as a measure of the subject brightness and the resistance control calibrated as an exposure meter.

Practical Advantages. An exposure photometer does not give the answer as quickly as an exposure meter because it often has to be standardized before it is used to measure the actual exposure. Its main advantage is its high sensitivity and small acceptance angle. This is about one-quarter degree and it allows the brightness of a very small area in the scene to be measured. There is another advantage of a small acceptance angle: the brightness of distant objects can be measured from the camera position. In this way the total brightness scale of the scene can be measured, which is often impossible with any other type of meter.

Enlarging. Grease spot photometers are made for use in enlarging to measure the actual brightness of any part of the negative area projected on the easel and hence the exposure and correct grade of paper.

In a typical enlarging photometer there is a translucent disc; the centre is lit by a lamp adjustable for brightness, and the surrounding outer ring by the light from the selected part of the negative.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PHOTOMETER LAYOUT. The eye views a grease spot illuminated by the subject from one side, and a small electric bulb (at controlled brightness) at the other. When both sides appear evenly matched (i.e., the grease spot disappears), the position of a diaphragm ring gives exposure readings. A, magnifier. B, grease spot. C, diaphragm controlling amount of light reaching grease spot from bulb. D, light bulb. E, potentiometer. F, battery. G, voltmeter. In some photometers the voltmeter circuit is replaced by a photo-electric cell system.

The brilliance of the two areas is matched by varying the brightness of the lamp in the photometer until there is no difference between the centre and the outer ring. This is done either by varying a resistance in series with the lamp or altering the distance of the lamp from the comparison spot. The latter method is probably more accurate because dimming the lamp by resistance changes the colour of the light and makes comparison difficult.

Once the two parts of the comparison field have been matched, a brightness factor for the selected part of the image is read off either from the resistance calibration or the scale along which the lamp is moved. The factor does not give the brightness in absolute units; it is simply a figure which can be translated into an exposure time for the particular grade and speed of paper in use by referring it to the calculator supplied with the instrument.

Comparison photometers of the type used for estimating camera exposures can be used to arrive at the exposure in enlarging, but they are not as a rule as convenient as those specially designed for the purpose. W.F.B.

PHOTOMETRIC EQUIVALENT Ratio of the mass of silver per unit area to the diffuse density. Thus

$$P = \frac{M}{D}$$

where P = photometric equivalent, M = mass Ag in grams per dm^2 and D = diffuse density. The photometric equivalent varies with the type of emulsion, with the exposure level, with the degree of development and with the conditions of drying.

The latter criterion is the reason why drying marks, or marks of different density from surrounding areas, are sometimes formed in areas which have received uniform exposure and have been developed to uniform density in the wet stages of processing.

See also: *Drying.*

PHOTOMETRY. Measurement of light in terms of the intensity of a standard light source. Measurements are made by comparing the intensity of the given light source with the light given by a standard candle. If the illuminating power of a light source 2 feet away from a surface is the same as that given by a standard candle one foot away, then, by the law of inverse squares the light source has an intensity of $2^2 = 4$ candle power.

Photometry plays an important part in sensitometry—i.e., the study of the effect of varying exposure on the photographic emulsion.

PHOTOMICROGRAPHY

Process by which photographs of minute objects are made with a camera and microscope. It should not be confused with microphotography, the process used for making minute photographs of large objects.

In 1835 Fox Talbot, applying his experimental process of Photogenic Drawing to the solar microscope, obtained photomicrographs of such objects as an insect's wing, magnified 17 times in linear dimensions. The date of 1837 which the Rev. J. B. Reade claimed for his earliest photomicrographs is refuted by his recently discovered letter to his brother, and early 1839 must be taken as the correct date. Friedrich Gerber of Berne obtained enlarged photographic images of microscopic objects on paper sensitized by his independently devised method, before February 1839. Alfred Donné made photomicrographs on daguerreotype plates, of sections of bones and teeth in February 1840, and subsequently he and others took photomicrographs of medical specimens. In July 1840 John Benjamin Dancer photographed a flea magnified by means of a gas microscope large enough to fill a 7 × 5 in. daguerreotype plate. J. Delves, a member of the newly founded

Microscopical Society, successfully took photomicrographs by the wet collodion process in 1852. Thereafter, photomicrography was extensively practised.

BASIC SET-UP

There are always three main units in any set-up for photomicrography: a lamp system for illuminating the specimen, a compound microscope, and a light-tight extension to hold the sensitive material. These three components, fixed rigidly together, make up a photomicrographic optical bench.

This optical bench may be arranged vertically or horizontally; the problem is much the same as in choosing between a horizontal and vertical type of enlarger. The horizontal bench can be made absolutely rigid, and it presents fewer constructional problems. The vertical set-up, however, takes up less space and if it is rigidly constructed it is capable of just as fine work as the horizontal type. In either case absolute rigidity is essential because the slightest tremor at the moment of exposure will ruin the result. It is difficult to make a vertical column rigid unless the top end is anchored to the ceiling by a bracket.

Vertical instruments are useful for photographing liquid preparations. They possess the further advantage that if something of interest is found during visual examination of a specimen, a photograph can be taken without disturbing the set-up. With a horizontal bench, the mere act of turning the microscope to the horizontal position is almost certain to upset the position of the object.

SIMPLE MICRO SET-UP. This uses a normal camera, focused at infinity. The microscope is focused visually, and the exposure found by trial and error. A table lamp serves as the light source for the substage condenser. Such an arrangement is suitable only for low-power work.

OPTICAL BENCH ARRANGEMENTS. Top: Horizontal optical bench. Is comparatively easy to construct, but takes up a lot of bench room. The microscope lamp directly illuminates the condenser. Bottom: Vertical optical bench; compact, but difficult to construct for the amateur in a sufficiently rigid form. A mirror directs the beam from the lamp into the condenser The camera is usually part of the unit.

The Camera. The camera is no more than a light-tight box fitted with a focusing screen and a plate or film holder, capable of light-tight connexion with the eyepiece of the microscope.

In the simplest form of set-up, any camera may be used if its lens is set to infinity and it is supported close against the eyepiece of the microscope after the specimen has first been focused visually in the ordinary way.

Special eyepiece cameras are made to fit over the draw tube and require no external support. Most makers of miniature cameras supply adaptors so that the camera, minus its lens, can be fixed on to the end of the draw tube of a microscope. A double or triple extension plate camera with the lens removed can also be used in the same way.

The Microscope. Practically any good compound microscope can be used. The main things to look for are rigidity of all parts, freedom from backlash when focusing, and, for horizontal work, absolute steadiness when the microscope is tilted into the horizontal position. Since the excellence of the result depends on the optical equipment, all lenses should be of first quality. Apochromatic objectives with compensating eyepieces are best, but achromatic objectives and Huyghenian eyepieces will give excellent results with monochromatic light, produced by interposing a suitable filter (generally green) between light-source and microscope.

In photomicrography resolving power is more important than mere magnification. The resolving power of a microscope is its ability to separate the images of two points lying very close together. This resolving power depends upon the aperture of the objective given by its numerical aperture (N.A.) which should be as large as possible

The aperture of the substage condenser should be sufficient to provide adequate light for the objective of largest aperture likely to be used.

MICRO-ATTACHMENTS. Top left: *Complete optical system of microscope, micro-attachment, and miniature camera, used without the camera lens. A movable prism permits observation of the image.* Top right: *The micro-attachment itself.* Bottom left: *Attachment (with its own shutter) mounted on microscope.* Bottom right: *Attachment used with focusing stage and ground glass screen of miniature camera outfit.*

Illumination. The light on the specimen must be under complete control during focusing and exposure, so artificial light is nearly always used. Most specimens are prepared for microscopic examination in the form of thin sections through which light can pass easily. They can therefore be photographed by transmitted light. The illumination of opaque specimens by reflected light and of very transparent subjects are special techniques (see below).

Special microscope lamps can be purchased, but for many kinds of work other standard types of lamp can be adapted. For very simple subjects, an opal filament lamp from 60 to 100 watts will suffice, but for serious photomicrography a point source of light is required. This can be provided by a motor-car headlamp bulb (6 or 12 volts), or a bicycle dynamo bulb (6 volts), fed from a mains transformer of suitable rating. Better, though more expensive, light sources are the Pointolite lamp, the ribbon filament lamp, and the carbon arc.

The lamp is housed in a light-tight, well-ventilated house like that fitted to an enlarger. For the simplest work the lamp may shine directly on to the specimen, but for anything more critical, some form of condenser is always necessary to concentrate the light into a controlled beam. Most microscopes are equipped with a substage condenser, and a further condenser between the lamp and the microscope is advisable. Each condenser has some means of varying the aperture—generally by an iris diaphragm—and some provision for focusing. A typical lamp condenser consists of a biconvex lens of 3 cm. ($1\frac{1}{4}$ in.) diameter with a power of about 15 diopters (6·5 cm. or $2\frac{1}{2}$ ins. focal length).

The photomicrographic set-up always includes a holder for a filter between lamp and microscope.

Köhler's Illumination. This is the most usual method. It calls for a lamp condenser and a substage condenser, each equipped with an iris diaphragm. First, the lamp condenser is made to project a slightly enlarged image of the light source on the closed diaphragm of the microscope. The substage iris is then opened and a specimen is placed on the stage, and roughly focused. The lamp iris is stopped down, to give an aperture of about 3 mm. diameter, and the substage condenser is used to focus an image of this illuminated aperture on to the specimen. The eyepiece of the microscope is then removed so that the back lens of the objective can be examined.

The substage iris is then stopped down so that its image just appears within the rim of the back lens.

The substage iris is then correctly set for that particular objective.

The eyepiece is replaced, the camera is set up in the same axis as the rest of the apparatus, and the image is focused on the ground glass. This image should be surrounded by a sharply defined black circle—the image of the lamp iris. Adjusting this iris does not affect the brilliance of the image; it varies the size of the illuminated circle and it can be adjusted to give any desired field of illumination.

Bluish marks on the focusing screen show that the apparatus is not correctly centred. Uneven or poor illumination is corrected by moving the lamphouse backwards or forwards, and then correcting the positions of the rest of the apparatus.

TECHNIQUE

The photographic side of micro-technique is comparatively straightforward. Certain points do, however, differ from standard practice.

Focusing. The image is focused on the

NUMERICAL APERTURES

Focal length ...	$\frac{2}{3}$ inch 16 mm.	$\frac{1}{2}$ inch 12 mm.	$\frac{1}{4}$ inch 6 mm.	$\frac{1}{6}$ inch 4 mm.	$\frac{1}{12}$ inch 2 mm. oil-imm.

KÖHLER'S ILLUMINATION. Left: *The first condenser focuses an image of the lamp on the second diaphragm. The second condenser focuses an image of the first diaphragm on the specimen. Closing the first diaphragm decreases the illuminated area of the specimen.* Right: *Closing the second diaphragm decreases the cone of rays entering the objective, but not the illuminated area.* A, *first condenser.* B, *first diaphragm.* C, *second diaphragm.* D, *second condenser.* E, *specimen.* F, *objective.*

ground glass. Usually this is too coarse for accurate focusing, but an excellent focusing screen may be made by pencilling a cross in the centre of the ground side and then cementing a cover slip over it with Canada balsam. The result is a clear circle intersected by cross lines. The image is examined by means of a magnifying glass, and should be in focus together with the cross lines. This is best determined by moving the head from side to side while looking through the magnifying glass. If the image is not in focus, it will appear to move in relation to the cross. But when it lies in the same focal plane as the cross, both will move together. When that happens, the image is in sharp focus.

Depth of field in photomicrography is very small. It can only be increased by using an objective fitted with a small iris diaphragm, but this in its turn means poorer resolution.

Filters. Whenever filters are used, focusing is carried out with the filter in position.

Achromatic lenses are generally used with a green filter to hold back the out-of-focus rays. Filters are also used to differentiate between stained areas in prepared botanical and zoological specimens. The choice of the correct filter for any particular specimen relies on the fact that a filter causes its own colour to print light, and its complementary colour to print dark.

Unfortunately, biological stains do not transmit pure spectral colours so that some care is necessary in choosing filters if the final print is to show clear colour contrasts. Gelatin filters are supplied in sets for microscope work; while they give satisfactory service in this form if they are handled carefully, they are better cemented between glass with Canada balsam. This type of filter must be used between lamp and microscope, and not between microscope and camera.

Blue or violet filters are used over the light for photographing fine detail such as the markings on diatoms, and on the chitinous coats of insects.

For work of extremely high resolution, light of a shorter wave-length is used. For diatom photography a blue filter is generally good enough, but for really critical work ultra-violet light must be employed. This necessitates a light source rich in ultra-violet, such as a mercury arc lamp, and an optical system transparent to the rays. So work of this sort calls for quartz lenses and a special photomicrographical bench.

FILTER EFFECTS

Colour of Filter	*Gives Contrast with*	*Gives Detail with*	*Approx. Factor (Tungsten Light)*
Deep magenta or purple	Chitin, diatoms orange, green	Blue	×10–×15
Deep blue (tricolour blue)	Chitin, diatoms, red, orange, yellow	Blue	×15–×35
Blue-green	Diatoms, yellow (compensates achromatic objectives)	Green	×10
Tricolour green	Red, orange (compensates achromatic objectives)	Green	×6–×9
Yellow green	Compensating filter to absorb U.V. and excess red		×1½
Pale yellow	Compensating filter to absorb U.V.		×1½
Deep yellow	Blue, violet	Yellow	×1½–×2
Orange	Blue, violet	Red, orange	×2–×4
Tricolour red	Green, blue violet	Red, orange	×2–×5
Deep red	Green, blue	Red, infra-red	×8–×25
Magenta	Green	Blue, red	×2–×3

Negative Material. Photomicrography calls for negative materials with fine grain and high resolution. Suitable emulsions are now coated on plates, cut films and 35 mm. film.

Process plates or positive film are generally used for normal sized negatives. Photomicrographs on 35 mm. film are generally taken on a document copying type of film. All these emulsions give high resolution and extremely fine grain. Faster emulsions are used only when the subject or the set-up is likely to move.

Most coloured subjects and stained sections

have to be photographed on panchromatic plates or films. Infra-red plates are used for photographing certain insects and beetles where the important detail is obscured by a chitinous layer. (Chitin is opaque to ordinary light but transparent to infra-red.) For the same reason, infra-red plates and an infra-red source of light will resolve specimens stained with silver nitrate which is normally opaque.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Exposure. The correct exposure is found by making test strips. The back of a dark slide shutter is marked off into six equal strips with white paint. For the test, the light is switched off, the shutter is completely withdrawn, and then the light is switched on for 1 second. After 1 second the shutter is pushed in one division, and again after 2 seconds, 4 seconds, 8 seconds, 16 seconds, and so on. In this way each section of the plate receives double the exposure of the one before.

In some cases the exposure may have to be measured in minutes, not seconds. The plate is then developed and the best exposure selected by inspection.

Development. Process materials need no special fine grain development technique; sufficiently fine grain results from development in an M-Q developer or a hydroquinone-caustic where strong contrast is important. Fine grain treatment is only necessary with the faster emulsions.

Naturally, stained sections and similar coloured objects necessitate the use of orthochromatic or panchromatic material, but this is almost always of slow or medium speed. Length of exposure is not usually of great importance, but fine grain is. In addition, the material is processed to give fine grain.

Colour Photography. Photomicrographs in colour are made with Photoflood lamps and Köhler's method of illumination. A suitable filter is used to correct the illumination for the particular colour material. The specimen must be mounted in a colourless medium such as methyl methacrylate or polystyrene, and not in Canada balsam which always has a tint. Achromatic condensers are essential for such work and a compensating filter may be necessary to remove any residual background colour.

Magnification. For the greatest resolving power of the objective, the magnification should be 300 times the numerical aperture. The maximum permissible magnification is about 1,000 times the N.A., so, in practice, a figure of about 600 times the N.A. is aimed at.

The magnification is measured directly by focusing the image of a stage micrometer on the screen. A stage micrometer is a microscope slide marked off in hundredths of a millimetre. The magnification is then given directly by measuring the length of the image of a one millimetre division with a millimetre rule laid on the focusing screen. An approximate figure can be arrived at by using the formula:

Total magnification = objective magnification × eyepiece magnification × camera extension (cm.) ÷ 25 (or ÷ 10 when measuring in inches).

The objective magnification is approximately

$$\frac{160}{\text{focal length (mm.)}} \quad \text{or} \quad \frac{7}{\text{focal length (inches)}}$$

The eyepiece magnification is generally marked on it.

Example: A 12 mm. objective of N.A. 0·35 is used with a 6× eyepiece and a 50 cm. camera extension.

$$\text{Objective magnification} = \frac{160}{12} = 13{\cdot}33\times$$

$$\text{Total magnification} = 13{\cdot}33 \times 6 \times 50 \div 25 = 160\times$$

So to obtain the desired magnification of 600 × N.A. = 600 × 0·35 = 210 ×, the final print will have to be enlarged from the negative a further 210/160 = about $1\frac{1}{3}$ times.

The upper limit of magnification for a 35 mm. camera is usually reached by enlarging to about whole-plate size ($6\frac{1}{2} \times 8\frac{1}{2}$ ins.). Magnification produced by the eyepiece does not increase resolution, it merely increases the size of the image.

Preparing the Specimen. Specimens like pollen, insect eggs, or the wing of a fly are examined dry. Some thick subjects have to be mounted in a cell on the slide before being covered by a cover-glass. But most specimens are sandwiched between slips of glass with a drop of water. The cover-glass is slipped carefully over the specimen so as to exclude air bubbles.

Dilute glycerin is sometimes used instead of water where there is a risk of evaporation during exposure.

Most botanical and zoological specimens must be teased apart with needles, or cut into very thin sections before mounting between glass. Sections may be cut with a flat-ground razor, the specimen being held in the hand and kept wet by constantly dipping it in water. For accurate preparation of slides on any scale, however, a microtome (a form of adjustable mechanical slicer) is more convenient.

Considerable skill is needed to prepare permanent slides, and only the general procedure can be outlined here. First the specimen is killed and its appearance fixed with dilute alcohol or formalin. Sections are cut at this stage. The specimen is left in the fixing fluid until required. As the object is saturated with alcohol it will accept alcoholic stains, such as safranin.

Superfluous stain is washed out with more alcohol, and the alcohol is removed by washing in water.

The section will now accept an aqueous stain, such as Delafield's haematoxylin. Any excess of this is removed by washing in water. The specimen is then immersed in alcohol of various strengths, e.g., 35, 50, 70, 85, 95, and 100 per

cent, starting with the weak solution and gradually bringing the specimen up to the strong solution. This removes the water.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The cell contents are opaque at this stage and must be cleared by immersion in clove oil, followed by xylol. The thinnest and best sections are then mounted on a slide and covered with a drop of Canada balsam in xylol. The cover slip is then placed in position, and the slide placed in a dry dust-free place until the balsam has set hard and the slide is safe to handle.

Opaque Specimens. Opaque specimens such as are found in metallurgy may be illuminated by directing a beam of light from the lamp so that it just grazes the surface. In this way every tiny surface irregularity is thrown into sharp relief. It is more usual, however, to employ a vertical illuminator, a special type of objective which receives a ray of light through the side, reflects it vertically down on to the object, and then transmits the rays as they are reflected upwards, towards the eyepiece.

With this type of illumination the loss of light is so great that a high-power light source such as a carbon or mercury arc is usually necessary.

Very Transparent Subjects. Dark ground illumination, used for very transparent objects, can give useful and beautiful results. It is produced by a special substage illuminator or the usual substage condenser fitted with a central stop.

In both systems only the marginal ring of rays is focused on to the specimen. When the rays cross and diverge they do so at such an angle that none of them enters the objective. But where the rays are refracted by the specimen, some of them are directed upwards and enter the objective. The result is a brilliant white image on a black ground.

Exposures are long, even with a powerful light source such as an arc lamp or a Photoflood.

Exposure is controlled by switching the light on and off, or by interposing a card between lamp and microscope to avoid movement or shake. For critical work it is found that practically every shutter introduces vibration.

DARK GROUND ILLUMINATION. A central stop between lamp and condenser cuts out the central cone of rays. The marginal rays illuminate the specimen, but do not enter the objective.

SPECIAL EQUIPMENT

Much of the manufactured photomicrographic equipment is intended for such specialized users as industrial research laboratories, hospitals, and universities. But there are three more or less standard types.

Horizontal Equipment. This type of equipment consists of a massive base carrying a lamp-house with condenser and iris, a microscope, and a camera capable of considerable extension. The lamp is usually a high-powered point source or a carbon or mercury arc. All optical units have centring screws by which the whole apparatus is lined up before use. The bed may be mounted on shock absorbers and generally carries remote control rods so that the objective can be focused from behind the focusing screen.

Vertical Equipment. The conventional vertical set-up consists of a camera and microscope running on vertical rails attached to a massive column, with a lamp system on horizontal rails in front of the microscope. The camera has a reflex screen for focusing and the microscope may have a reflex eyepiece so that the image can be observed during focusing. The microscope mirror must always be used.

The Eyepiece Camera. The eyepiece camera fits over the draw tube of an ordinary microscope. It often carries its own shutter and eyepiece so that the image may be observed after the dark slide has been fitted. When the reflex eyepiece is focused accurately on the cross hairs, the instrument is adjusted for the user's sight. The makers incorporate all necessary corrections for the alteration in the tube-length of the microscope. (The optical system of a microscope is corrected for a certain tube-length, usually 160 mm., and if triple nose-pieces or other attachments are added later, the draw tube must be used to correct the tube length.)

The Electron Microscope. The electron microscope is based on an extension of the principle that the shorter the wavelength the higher the resolution. The "light" is an electron stream, and the "lenses" consist of magnets and electrical condensers which focus the beam. The increased resolving power makes it possible to work magnifications up to 100,000×. A camera is normally built in to the instrument and used for making permanent records of the image—formed in this case on a fluorescent screen.

Phase-Contrast Microscopes. For dealing with highly refractile specimens there are now on the market phase-contrast microscopes, or attachments for converting an ordinary microscope into a phase-contrast type. These depend on a novel principle—that of slowing down some of the light rays. A.Ja.

Books: *Amateur Photomicrography*, by A. Jackson (London); *Practical Photomicrography*, by J. Bergner, W. Mehliss and E. Gelbke (London); *The Technique of Photomicrography*, by D. F. Lawson (London); *Photomicrography, Theory and Practice*, by C. P. Shillaber (London).

PHOTOMONTAGE. Composite photograph made by cutting out and pasting together several separate photographs to achieve a particular effect—e.g., to convey an over-all impression in a portrait by combining several aspects of the same face. Alternatively, photo montage may be used in producing photographs covering a very wide angle of view—e.g., in panoramas.

Photomontage was largely practised by pictorial photographers, originally to obtain effects not otherwise possible with the comparatively slow and "colour-blind" negative material. The first to practise photomontage (1858) was H. P. Robinson, most of whose elaborate composition pictures were scissor and pastepot productions. In the 1860s and '70s many amateur artists made photomontages by combining (usually) other people's photographs with their own watercolours. This technique was later forgotten but re-introduced by George Grosz and John Heartfield in 1915. It is nowadays chiefly used in advertising.

PHOTO MURAL

A photo mural is a photograph that covers an entire wall or section of wall as a decoration. There are two ways of applying a photographic image of the requisite size to the wall surface: the negative is enlarged on to bromide paper in sections and the sections are assembled and stuck on to the wall; the wall may be sprayed with sensitized emulsion and the negative enlarged directly on to it.

Both methods are practised by firms specializing in photo mural work. The second method can only be applied by such specialists, but the first method is within the resources of the normal professional who only wants to use it occasionally. It is easier, however, if a few extra items of equipment—e.g., large dishes and bowls, provision for drying and trimming of the prints—are available.

Uses. One of the most popular applications of photo murals, apart from their use as display pieces, posters, and exhibition features, is as a wall decoration. In hotels, reception halls, and even private houses they are frequently used to give an impression of space. A scene consisting mainly of middle distance and distance is made to cover a whole wall, and enlarged to its natural proportions as viewed from the room.

Sometimes the scene is set in a dummy window frame so that it appears as though seen through an actual window.

Hand colouring may strengthen the impression.

Scenes suitable for this type of photo mural are panoramas of well-varied landscapes: a range of distant mountains seen across a valley, a distant vista of skyscrapers or a fringe of palm trees along the edge of a lagoon. A suitable mural for an air-line booking office would be a photograph taken from an aircraft of a cloudscape in sunlight. In a private house, a blank wall—e.g., of a basement lounge—might be decorated with a view of mountains mirrored in a lake to give a feeling of spaciousness.

The viewing distance must be carefully considered in the production of murals. The effect of the display will be lost if the print is too large and the viewer cannot stand far enough away to obtain a comprehensive view.

The Negative. Because of the great scale of enlargement, the negative must be critically sharp to allow for some inevitable loss of definition in enlarging, and as thin as possible so that printing time is kept within reasonable limits. If it is inclined to be dense, it pays to make a thinner copy negative as big as the enlarger can take, and preferably from an enlarged and retouched print.

It is very much easier to print the whole negative area in one exposure if the space to be covered is not too big for the enlarger used. If it is not possible to find a big enough wall space in the darkroom (or a room that can be darkened) or the enlarger cannot be set up far enough away from the wall to project the whole negative to the required size, then the picture will have to be made in two or more sections. To do this, the negative must be copied in sections on to the required number of plates so that each section occupies as much of the plate area as possible. The plates are all exposed and processed together, or at least under identical conditions.

Paper. In general, glossy paper should be avoided because light reflected from the surface is distracting. White or ivory base papers with a semi-matt or lustre surface have an excellent luminosity and depth of tone and will readily accept retouching and colouring pigments and dyes.

Enlargers. A horizontal enlarger is preferable, though a vertical enlarger with a rotating head can be used. The lens must be of good quality and of a sufficient focal length to cover the negative adequately.

Any unevenness of illumination must be rectified. There are two ways of doing this:

(1) A small circle of fine tissue paper can be stuck to the top of the condenser and the edges of the paper notched to reduce any sharp difference in density, or

(2) A compensating screen can be made by placing an unexposed slow plate in place of the diffusing screen and briefly flashing the exposing lamp. The plate is then developed in a very weak developer to a very low density. The density of the resulting image is greatest

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

where the light is brightest, and, when it is correctly exposed and developed, it exactly cancels out any uneveness in illumination when inserted in place of the diffusing screen.

Processing Dishes. The normal 18 × 20 ins. dishes are suitable for see-saw processing of lengths of paper up to 3 feet long by 20 ins. wide. Larger and deeper dishes are essential for processing long lengths of paper by the roll method.

A simple method of making temporary dishes of a suitable size is to cover a wooden foundation with waterproof plastic. For the base, a large sheet of wall board or plywood is used, and a raised rim is built around it by fastening lengths of 1 × 2 ins. batten along the edges to form a closed rectangle 2 ins. deep. The plastic sheet material sold by the yard for curtains and table coverings makes a satisfactory waterproof lining. It is simply laid on the wooden base and tacked into position along the outside edges of the side battens.

The size of the dish that can be constructed in this way is limited only by the width of the materials, but both wall board and plastic are made in at least 36 ins. width which is ample for making a dish to handle 20 ins. wide photo mural printing paper. (At least 10 ins. must be allowed on the width of the plastic sheet to include the sides and turnings.) For processing 40 ins. wide paper it will be necessary to join two widths of wall board and cover the dish with 54 ins. wide plastic sheet. Such dishes cost only a fraction of the price of the proper article and the materials can be used again for other purposes.

Printing Surface. If possible the mural should be printed in a single exposure. For this, it is necessary to have a printing surface at least as big as the finished mural with enough distance in front of it to allow the enlarger to be set up to cover that area. There is nothing better than the wall of the room, but if a suitable wall is not available, a surface must be constructed with wall-board on battens.

The finished surface must be free from bumps or unevenness and the enlarger must be set up accurately in position with respect to it. This is best done by removing the negative and measuring up the sides and diagonals of the projected rectangle of light cast by the negative carrier. If only a part of the negative is to be enlarged, then the equivalent rectangle should be marked out in ink on a clear piece of negative material—or scratched on an old dense negative. This rectangle is then projected to the required size and checked for equality of diagonals and opposite sides.

If the photo mural must be printed in sections, when all the sections are assembled it must look as though the whole picture had been enlarged at one time on a single sheet of paper. This means that each section must match the next in regard to its scale, its printing density, and its contrast.

PHOTO MURALS. Top: *The original negative must be critically sharp and reasonably thin.* Upper centre: *Usually it is advisable to prepare a copy negative from the original negative, as large as possible. Where very great wall areas are to be covered, the copy negative may be made in sections.* Lower centre: *The enlargements are made on to strips of paper pinned to the wall. Pins should be placed at an angle away from the lens, to minimize shadows.* Bottom: *The final prints should have sufficient overlap at the edges of each section to permit easy assembly when it is mounted in position.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Scale. Once the negative has been set and focused in the enlarger, nothing must be moved until the whole job is finished. It is extremely difficult to re-focus a negative to give a matching print. Even when the prints are all exposed at the same scale of enlargement, the greatest care must be exercised in processing them or one may stretch more than another and refuse to register with it. This applies particularly to paper that is squeegeed while it is wet; extra pressure on one sheet will press it out larger than its neighbours.

It is also necessary for the lens to have a flat and undistorted field. Any difference in magnification between one side of the field and the other will show up as soon as the prints are joined up.

Printing Density. The prints will have the same density only if they are exposed for the same length of time under exactly comparable conditions. This means that the enlarger illumination must be absolutely uniform measured over the actual image area, and not simply on the negative. Unless the printing density is the same, a fully-exposed black alongside a corresponding but under-exposed black on the adjacent section of the picture will show the join at once.

Tone. Even when all sections of the picture have had the same exposure, they will not necessarily give blacks of the same tone if the temperature of the developer changes during processing or the solution is worked to the point of exhaustion, or if, by faulty manipulation in the solution, one print gets more development than another. Furthermore, any "dodging" carried out on one print must be repeated exactly when the adjacent section is being exposed or there will be tone differences between the two.

Preparation. In the simplest case, the complete mural will be made in a single exposure by projecting the whole of the negative image on to the paper at once. The dimensions of the mural should be chosen so that it can be covered with the minimum number of sheets or strips of paper, allowing for about a ¾ in. overlap—e.g., a 6 × 10 foot mural would be printed on two 10-foot lengths of 40 ins. wide paper.

The boundaries of the picture are marked on the printing surface, allowing for an inch in 40 stretch in the paper after processing. The enlarger is then set up with the negative in position in the carrier and adjusted until the required picture just fills the marked space.

If the mural must be printed in sections, each section is copied on to the largest negative that the enlarger will take. The size of the first section is marked out on the printing surface and the corresponding negative is adjusted to fill it. Once this has been done, the subsequent sections are printed without adjusting the scale of enlargement again, otherwise the adjacent sections will not match. It should always be possible to print each section on not more than two widths of paper. An allowance of up to 2 ins. should be made down the adjoining edges of the sections to allow for overlapping.

Each negative should be masked down to little more than the exact printing area to cut down the unwanted light as much as possible.

Printing. When the image has been focused and adjusted to fit the area, the lens is stopped down until the definition is satisfactory right to the corners of the picture. Test pieces of paper—about whole plate size—are then exposed in the centre and corners of the picture area to arrive at the right exposure. The test pieces should include representative highlights and shadows and should be cut from the actual roll of paper to be used for making the prints. Each test piece is developed right out, and the exposure (or local control) adjusted until it gives a fully graded image under these conditions.

Once the exposure has been determined, the actual printing can proceed. Whether the mural takes a single exposure, or has to be covered in several, the method is the same. The first length of paper is pinned in position over the lower half of the image area. Then, before pinning up the second half, about an inch is trimmed off along one of the edges to take care of the defective emulsion occasionally found at the extreme edge of this type of paper. The trimmed edge is then lapped about ¾ inch over the adjoining edge of the first length and held in close contact with ordinary pins, placed to cast the smallest possible shadow. (These shadows are subsequently touched out with dye or pigment.) If the paper is left rolled up, emulsion side out, for an hour or two before pinning it up, it will lie flat to the wall.

The exposure is then made by switching the enlarger lamp on and off. It is essential for the whole set-up to be perfectly steady before making the exposure; the slightest vibration at this scale of magnification hopelessly blurs the image.

Processing. One of four methods may be used for processing the exposed strips. For the first three methods the paper should be presoaked. All strips must be developed under exactly the same conditions and for exactly the same time as all others for the same mural.

(1) Large dish method. If a large enough tray is available, the strip may be processed flat in the normal manner and should be covered with developer quickly and evenly to avoid uneven development. Another method is to fold the strip in half, emulsion side out, and then fold the doubled strip once more. It is now one quarter of its length and can be processed in a dish of a smaller size by regularly reversing the second fold so as to bring the inside and outside emulsion surfaces into contact with the developer in turn.

(2) See-saw method. This method may be

used by one operator for strips up to 4 feet in length; longer lengths require three operators, one at each end and the third to manipulate the loop fully immersed. To facilitate handling, and reduce the danger of tearing, the ends of the paper should be clipped to wooden rods running the full width of the strip.

CC-0. Agamnigam Digital Preservation Foundation and Eklavya

(3) Deep-dish method. This method is recommended for processing long strips, and requires one operator. The paper is completely immersed during pre-soaking while being continually unrolled and re-rolled from end to end. The unrolling and re-rolling are repeated throughout the whole period of development and fixing; constant movement and complete immersion are essential to even developer action.

(4) Brushing method. A developer with no tendency to stain during prolonged development—e.g., a glycin type—must be used for this method.

The strip should be laid on a non-absorbent surface and swabbed with developer as evenly as possible. Full development of up to 6 minutes may be given to allow areas wetted at different times to even out. Excess developer should then be squeegeed off and an acid stop-bath flooded on.

After a few seconds the stopbath should be drained off, and the fixer swabbed on for the full fixing time, ensuring a continually fresh supply of fixer.

The exposure may be shortened slightly and development time extended should the standard development times prove inconveniently short.

To ensure even density of strips the temperatures of all processing solutions must be maintained at a constant level.

A plain acid fixing bath without hardener should be used to avoid the possibility of the emulsion cracking should the paper be kinked after drying.

Normal washing in running water is preferable; alternatively, the strips should be soaked for 5 minutes in each of twelve changes of water. A hypo test should be made if the prints are for permanent display.

The strips are best dried by clipping them at intervals along the whole length to a stretched cord.

Mounting. If prints are to be mounted direct on to a wall the tendency to contract on drying will not matter. But if mounted on panels for temporary display, the panels should be strongly braced to prevent warping. Alternatively, a sheet of wet kraft paper should be pasted to the back of the mount at the same time as the enlargement is mounted. This will counterbalance the pull of the paper on the other side and leave the mount flat.

If the prints are to be mounted on an absorbent material, the surface must be well sized beforehand. A sheet of muslin may be pasted over the wall to provide a continuous mounting surface.

The adjacent edges of the strips may be trimmed butt or mitre jointed—in the same way as a paperhanger puts paper on a wall—or they may be overlapped. One method which produces an almost invisible join is to strip the paper support away from the emulsion for about ¾ in. along one edge, and to cut away the same amount of emulsion from the corresponding edge of the adjacent strip. (A suitable amount of overlap of the image must be allowed in printing.) The emulsion of one strip is then pasted over the paper base of the strip next to it. The final effect is of an unbroken emulsion surface stretching right over the join. It is doubtful whether such exact methods are justified in photo murals that are to be looked at from a distance, but they may be worth while on the walls of living-rooms, etc.

To apply the paper, it is first soaked in plain water to get it limp and, after draining, it is laid face down and well brushed over with a good water paste, strained if necessary to remove any solid particles. It is then carefully lifted and smoothed into place with a wet flannel rolled around a block of wood and constantly dipped in water to make it slide easily. Any excess paste that squeezes out can be sponged off later. When all strips have been fitted into position, the work is allowed to dry for a day before retouching and finishing.

Finishing. Slight blemishes are retouched with normal bromide spotting dyes, or with water colour. Small areas can be retouched with pencil, provided the surface of the print is subsequently to be protected. Large areas are best worked up with an air-brush.

Oil or water colour can be applied by air-brush, camel-hair brushes, or cotton wool on orange sticks. Colouring work should be frequently viewed from a distance to verify the general effect.

A coat of clear cellulose lacquer provides maximum permanence and weather-proofing, and the lacquer should be applied by means of a paint spray-gun. For outdoor enlargements both print and mount should be sprayed.

In Situ Method. The method of enlarging the negative direct on to a sprayed-on wall-coating of emulsion is a highly specialized techique that is beyond the resources of the ordinary studio.

First of all the surface must be prepared to ensure that no chemicals in the wall or its protective finish can affect the photographic image in the course of time. It may be necessary to spray on a sealing coat before applying the emulsion. Some provision must also be made to collect the solutions that are swabbed on to the surface later.

After the room has been completely blacked out and equipped with a suitable safelight, the emulsion is sprayed on to the wall surface with a special type of paint spray-gun silver plated on all surfaces in contact with the

emulsion. So that the operator will be able to tell which parts he has covered, the emulsion incorporates a dye—e.g., a red dye which appears as a dark tone under a light green safelight. The dye is water-soluble and is removed in the course of processing.

The emulsion is supplied as a dry powder which is mixed with warm water immediately before use. It is applied under carefully controlled conditions of room temperature and humidity. When the emulsion dries the negative is enlarged on to it in a single operation, after which it is processed by swabbing or spraying the solutions on to the surface. After washing and drying, the surface is finally sprayed with a protective finishing coat of transparent varnish. A.E.S.

PHOTOPLASTIC RECORDING. A reusable, grainless electrostatic recording process using thermoplastic photoconductive polymeric layer which when molten, deforms in accordance with the pattern of electrostatic charges.

See also: *Thermoplastic recording.*

PHOTO-REPORTAGE. Use of photography to supplement or replace accounts of events and places of current interest written for publication—e.g., in newspapers or magazines.

See also: *Freelance photography; Magazine photography; Photo journalism; Picture series; Press photography.*

PHOTO RESISTOR. Alternative term for photo-conductor, a substance which changes its electrical resistance under the influence of light. With most photo-resistors the resistance decreases the greater the light intensity falling on the resistor. One of the best-known photo-resistors for photographic purposes is the cadmium sulphide cell.

See also: *Photo-electric cell.*

PHOTOSCULPTURE. Method of automatic sculpture based on a camera image or images of the subject. Since the middle of the last century workers in various countries have attempted to use the camera for producing either bas reliefs or solid sculptures. Most attempts have succeeded in producing results of a sort, but all were too complicated and costly to survive. Some systems were almost completely automatic; the camera images being translated directly into the corresponding solid form. In others, the images were no more than a guide to the operations of one or more sculptors.

Willème's Method. François Willème (1830–1905), a French painter and sculptor, took out patents for a method of photosculpture in 1860 and received enough support to found La Société Générale de Photosculpture de France (the French General Society of Photosculpture) and erect a pretentious establishment in Paris. He employed a staff of photographers and sculptors whom he trained in the technique.

The studio consisted of a circular room with a glass dome. Twenty-four cameras were disposed regularly around the perimeter and focused on the centre of the room where the sitter occupied a raised dais. A silver ball suspended from the exact centre of the dome immediately over the sitter's head provided a common reference by which all the negatives could later be registered.

All the cameras were operated simultaneously by a common shutter control and an exposure of about 10 seconds gave twenty-four negatives, each showing a profile of the subject from a different angle. These negatives were then projected to the required finished size and a set of templates traced from the projected images, all the templates being registered on the image of the ball and the cord by which it was suspended.

The templates were mounted in turn on a pantograph set up in front of a mass of modelling clay fixed on a rotating platform. The platform could be fixed in any one of twenty-four positions corresponding to the camera angles from which the set of photographs were taken. Each of the templates was set up in turn in such a way that when the operator traced around it with the stylus of the pantograph, he moved a tool which shaped the clay to the same profile. When one profile had been carved out in this way, the clay was rotated into the next position and the corresponding template set up in the pantograph.

The process was repeated until all twenty-four profiles had been cut in the clay, and at that stage the work was continued by hand. A considerable amount of handwork was necessary to fill in the shape between one profile and the next and to add the depressed features—e.g., eye sockets and nostrils—which were bound to be left out by this method. The clay could then be used to make a mould from which copies could be cast in plaster or metal.

In spite of the many practical difficulties and the large amount of skilled workmanship, the method was a craze for a time, and many people patronized the studio, among them such notables as Theophile Gautier, the leading actors of the day, and the entire Spanish royal family. But the enterprise could not pay its way and had to close down in 1867. Various

improvements on the method were proposed, notably by Poetschke (1891) and Selke (1892), but were not applied on a commercial scale.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Baes' Method. Carlo Baes, an Italian sculptor, developed a method of photosculpture at the beginning of the century and published an account with a photograph of his studio set-up in 1908. His method was to illuminate the subject by a light source and a ring of mirrors in such a way that the illumination increased uniformly from the front to the back of the subject. One exposure was made in this way and then another was made with the lighting reversed so that its intensity increased from the back to the front.

The two negatives were printed in register on to bichromated gelatin which was processed to make it swell selectively and form a relief image. By combining two complementary negative images in this way all effects of colour and lighting were neutralized and the result was a pattern of tones which varied in density with the relief of the subject.

This method is only suitable for portrait heads of about 3 ins. in height because the relief produced is not sufficiently pronounced to resemble anything like a solid object.

Edmunds' Method. In 1921 H. M. Edmunds published a process in which a spiral light trace was projected on to the subject from a point close to the camera lens. In the resulting picture the spiral was distorted by the irregularities in the surface of the subject. Up to a point, the distortions indicated the shape of the surface and formed the basis for the semi-automatic carving operation that followed.

In the carving process, the distorted spiral image was scanned by a low power microscope linked to a pantograph through which it controlled a power-driven engraving tool. By this means any suitable material could be shaped to a relief image of the subject.

This method possessed the advantage that it reproduced cavities that are inevitably filled in by the various methods in which the illumination falls across the subject from the side.

Givaudan's Method. The inventor of this method, which was described in 1926, called it photostereotomy because in effect it divided up the subject optically into a number of parallel slices. The subject was surrounded by a system of five light sources shining through narrow slits, the total effect of which added up to a thin continuous line of light. This line of light illuminated the edge of an imaginary section of the subject cut parallel to the focal plane to the lens. The light sources were mounted on a sliding carriage so that it was possible to illuminate and photograph a series of sections from the front to the back of the subject. The negative image of each section was printed and the profile cut out. When all the profiles obtained in this way were assembled, the result was a relief image.

By making very small shifts of the lighting between exposures—i.e., making a large number of profiles—the final result was reasonably continuous. In practice, Givaudan combined as many as sixty profiles printed on paper 1/10 mm. thick to form a relief image 6 mm. thick.

It was also possible to insert suitable spacers between the profiles to increase the thickness to its natural proportion, and by combining such reliefs made from both sides of the subject, the result was equivalent to a sculped figure.

Sculptography. A method attributed to Japan and subsequently applied in the United States was described in 1934 under the name of sculptography. In this, the sitter occupies a chair in a dark room on a turntable which can be complete rotated once in four seconds. A thin vertical line of light is projected on to the subject and photographed with a cinematograph camera. The angle between the light projector and camera axes is about 30°, so that the line of light as seen by the camera bends with the contours of the subject. (If both axes lay close together, the camera would see only a vertical line, no matter what the position of the subject.)

The resulting cine record is of a succession of profiles, each taken from a slightly different angle. These profiles are enlarged separately and cut out either mechanically or by etching, and assembled with packing between to form a solid figure. The ridges formed by the edges of the individual profiles are filled with wax and casts are made in the usual way.

Of all the methods that have been proposed or tried, this appears to be the most promising, but like the others, it has never become a widely followed commercial proposition. F.P.

PHOTO-SECESSION. A secession from the New York Camera Club in 1902, led by Alfred Stieglitz with Alvin Langdon Coburn, Frank Eugene, Gertrude Käsebier, Edward Steichen, Clarence H. White and later 41 others. Their aim was to break with conventional pictorialism, to explore fresh photographic subject matter, and to concentrate on rendering the subtleties of light. The Photo-Secession was affiliated to the Linked Ring.

PHOTO-SENSITIVE GLASS. Glass made sensitive to ultra-violet radiation by the addition of certain heavy metal compounds. Exposure forms a latent image which becomes visible on heating the glass to about 600°C.

See also: *Glass (photo-sensitive).*

PHOTO-SENSITIVE PLASTIC. Polymer-type plastics which are made light sensitive and under the influence of light become insoluble or change colour.

See also: *Plastics.*

PHOTOSENSITIVITY. Generic term for the reactions of materials and processes to light energy.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PHOTOSTAT. Proprietary name for a copying camera and process designed to produce quick and accurate copies on a commercial scale. It is mounted on a pedestal with all the necessary controls and its own easel for supporting the document to be copied.

The sensitized material used is a special highly sensitive paper carried on a reel in a magazine in the camera. An automatic processing unit develops and fixes the exposed prints so that they only require washing in daylight before being dried. The Photostat, like the reflex printing and camera processes, produces a negative from which contact copies can be made.

If large true-to-scale positives are required, the first camera picture is usually taken on special film. By using an attachment that converts the Photostat into a projector, enlargements from the film can be made to any convenient scale. Several manufacturers market machines of the Photostat type; their names may vary, but the principle is the same in all cases.

See also: *Document copying.*

PHOTO-STEREO-SYNTHESIS. Method of producing an image which gives an impression of stereoscopic relief when viewed normally. The image consists of a number of positive transparencies made by taking a series of photographs of a still subject, each photograph showing only a single plane sharp. After each exposure the camera is moved nearer to the subject so that the scale of reproduction is the same for each plane. The resulting transparencies are then superimposed so that the sharp planes depicted occur in the same relationship as in the original subject and are proportionately spaced. The impression of relief is appreciable from one observation point only.

PHOTOTELEGRAPHY. Nowadays the transmission of pictures by wire and radio is an everyday occurrence; almost every newspaper possesses at least one transmitter and receiver. Modern equipment produces pictures which are almost indistinguishable from the original, and for this reason many wired pictures are reproduced in our newspapers without any indication of the fact being given in the caption.

History. Picture telegraphy is by no means a recent technique. Attempts at the transmission of pictures by wire were made even before the development of Morse Code telegraphy for normal communication.

The first system was devised and demonstrated in 1842 by Alexander Bain, a Scotsman, using a set-up which satisfied in an elementary way the fundamental requirements for facsimile transmission as it is known to-day. Other early

PHOTOTELEGRAPHY. Top: *Transmitter. The picture is wound round a drum revolving at a fixed speed, and scanned by a light source and a photo-cell. The impulses are then superimposed on a carrier wave and fed into the line.* Bottom: *Receiver. experimenters were Shelford Bidwell (1881), Belin, Korn, Jenkins and Ferre. Even before the introduction of modern electronic valves, practical systems with commercial applications had been developed. These systems used a code for tone values and could transmit reasonably good half-tones.

With the advent of electronic techniques the transmission of half-tones was made much easier and from the early nineteen-twenties high quality picture transmission became a reality. At the present time the majority of equipment in use is manufactured by Muirhead in England, Belin in France, and Times and Acme in the U.S.A.

Transmission Principles. There is nothing difficult about the basic principles of picture telegraphy transmission. The picture to be transmitted is wrapped round a rotating drum, the surface of which is scanned by a spot of light which traverses it from end to end. Light reflected from the illuminated portion of the

picture is focused on to a photo-cell, thus producing a minute current which varies as the drum rotates and the light spot travels over areas of differing tonal density. This current is amplified and transmitted by line or radio to the receiving end. In the receiver it is made to vary the intensity of a spot of light which falls on a sheet of sensitized paper wrapped round a drum similar to, and scanned in synchronism with, the transmitter drum.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The photographic material used may be either paper or film, for by suitably adjusting the recording characteristics of the receiver the incoming signal can be made to record as a negative or a positive image.

Recent Developments. Portable picture transmitters now exist which can be used wherever a telephone line is available, enabling up-to-the-minute photographs to appear in newspapers. The technique of phototelegraphy is also used to transmit complete newspaper pages; the process takes only a few minutes, and allows a newspaper to be printed and published simultaneously in places hundreds of miles apart.

Direct Recording. One of the most notable advances has been the development of direct recording on electrosensitive paper. A recorder of this type uses paper in rolls sufficient for several hours continuous operation. The paper is drawn slowly between a rotating helix and a stainless steel blade, and a fluctuating current controlled by the received signal is passed through the paper at the point of intersection. The chemical action which occurs at the point of contact causes local darkening of the paper. The helix drum is maintained in synchronism with the transmitter drum and the picture is built up in a series of parallel lines.

The paper consists of a resin-bonded sulphite pulp paper of high wet strength and great absorbency, impregnated with an electrolyte and a colour-forming substance. Other chemicals are also added to intensify the colour and limit its spread.

The current decomposes the electrolyte and one of the products of the decomposition reacts with the stainless steel blade to form a ferric salt. This salt reacts with the colour-forming substance and colours the paper. The result is a black-and-white record instantly visible without processing. Tonal gradation is good, and although the definition of photographs received in this way is not as high as those received on photographic paper, it is good enough for newspaper reproduction.

This technique has the advantage that the received copy is instantly usable, no processing of any kind being necessary. Direct-recording machines are used extensively for the accurate dissemination of weather maps and information, there being no possibility of errors occurring during the transmitting/receiving process. Facsimile machines are also used in multi-branch offices for transmitting and receiving graphic material such as documents, drawings, diagrams, etc. H.S.

Books: *Facsimile*, by C. R. Jones (London); *The Transmission of Pictures by Radio*, by Cole and Small (London).

PHOTO-THEODOLITE. Special type of photogrammetric camera for applying the principles of trigonometrical surveying to record photography. The camera is equipped with means of accurately defining its position and the angle of view of the subject. A grid, giving accurate horizontal and vertical references, is superimposed on the plate at the time of exposure. The field of the camera lens is corrected with respect to the grid lines so that the dimensions of the subject can be accurately deduced. The principle on which the photo-theodolite camera works is that it is possible to determine the position in space of any point object from photographs taken from two different viewpoints when the angle between the two cameras and their respective positions are known.

Similarly, the shape of any solid object can be reconstructed by plotting the intersection of perspective rays from corresponding points on the separate images.

There are two types of photo-theodolite, the simpler in which the photographs are always taken with the plate vertical, and a more complex instrument which may be used with inclined plates.

See also: *Naval photography; Photogrammetry.*

PHOTO-TRANSISTOR. Transistor used as a light-operated switch. All transistors are photosensitive and are normally in an opaque container. In a photo-transistor the active part—a germanium wafer—is enclosed in a glass envelope. A light-diffusing filling of silicone grease ensures that any light falling on the transistor produces the same effect whatever its angle.

There are various ways of connecting a photo-transistor according to the function of the circuit. In the simplest type of circuit for straightforward on-off switching, two of the transistor elements, the emitter and collector, are connected in series with a relay coil and a D.C. supply of 12 to 18 volts. Under these conditions a typical circuit might pass a dark current as low as 300 microamperes, rising to 5 milliamps or more when light falls on the transistor.

Photo-transistors are used in photography as a basis for light-operated shutter release mechanisms and in slave units for multiple flash systems in which one or more separate flash units are triggered off automatically by the flash from the master unit.

See also: *Photo-electric cell.*

PHOTO TYPE-SETTING. (Film Setting.) Photographic method of producing a column or page of text in a single operation from a master photographic negative. Though first

proposed at the beginning of the century, it did not become a practical workshop method until the 1950s.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Filmsetter machines are fitted with one or more assemblies of master negatives (photo-matrices), containing all the characters likely to be required. Instead of casting molten type metal to form the printing characters, as in the conventional mechanical typesetting machines, the filmsetter machine projects light through its negative character matrices and forms photographic positive images of them upon film, at the required size and in the appropriate order, thus producing lines, columns and pages of text. The different type sizes are obtained by varying the projection scale.

Photo-typesetting is usually considered in two sections; true filmsetting for the mechanical, keyboard controlled, photographic composition of text matter; and photo-lettering for setting display headings, advertisement layouts, etc. There are a great many photo-lettering machines, varying from quite simple hand positioned devices to comparatively elaborate machines, but their purpose is different from that of the high speed filmsetter machines.

Filmsetter Machines. The standard keyboard operation is used which results in movement of the matrix to bring the selected character into position over a roll of unexposed film. An exposure is then automatically made so that the negative image is recorded on the roll of film. Subsequent operation of keys repeats this procedure, at the same time racking the projected images horizontally to build up each line. The result is lines of text recorded photographically on the roll of film; from this, ordinary line blocks or a negative for photo litho printing can be made.

One electronic machine carries the negative character images on a disc revolving at ten revolutions per second. A high speed flash freezes the movement of the selected character at the required instant as it passes the exposure position. The optical system of another machine projects eighty-eight character images (on any one of a number of photo-matrices) into one position at the film plane, a series of louvre shutters covering all but the required character while an electronic flash exposes it.

PHOTO-TYPE SETTING. Relative movement of lens and two prisms adjusts letter sizes and focus. Lateral traverse of mirrors moves images along image plane. A, negative matrix. B, shutter. C, lens. D, mirror assembly. E, film drum.

The lenses used in photo-type setting machines are specially designed and must be accurately positioned as critical definition is essential. Some systems use a turret of lenses to obtain various projection (or type) sizes.

The source of light usually resembles bulbs used in car head-lamps working at 12, 24 or 48 watts, or is an electronic flash tube. The useful light output is concentrated by a condenser lens system to give illumination over the area of the character in the master matrix.

The film is spooled up on to a drum (size of film used is determined by the width of column or page to be set). The film is then fed through the mechanism and held rigidly immobile during exposure. Corrections are made by deleting and inserting full lines. The film is then processed and a positive of the column or page is the final product.

There are six major film setting systems; three American, two British and one Dutch. Of these systems three have been evolved through the adaptation to photography of existing principles in hot metal type setting machines. The others make a completely new approach.

High-speed Filmsetting. Some electronic filmsetter machines can set photographic text images at speeds of the order of 30,000 characters per hour. This is much faster than a keyboard operator can work, so the keyboard output is recorded on punched paper tape, and the tape from a number of keyboards fed into one filmsetter machine. Corrections can be recorded on a separate tape, and fed into the machine by a tape merging system which automatically makes the required corrections at the right positions.

A further system under development is computer control. A computer can be programmed to govern the width of the film set lines, the word spacing and word splitting. Automatic machines are evolving which can even read typed manuscript matter and directly convert this into film set text without the need for a keyboard operator. This makes photo-type setting possible at extremely high speeds.

Photo-Lettering. Photo-lettering equipment for setting display matter and layouts is rather different from a film setter, though the basic principle is the same.

The unit is essentially a photographic enlarger, using a photo matrix containing all the characters of a particular type face in the negative carrier. This is projected on to a sensitive film or paper on a special easel which can be moved horizontally and vertically or angled in any direction.

Operation is manual and consists of locating the required letter on the negative matrix in a suitable central position. A red filter over the enlarger lens permits the placing of the image on the sensitive material in the required place. A white-light exposure records the letter, after which the easel is moved (and also the negative carrier) to bring the next letter in the appropriate position relative to the previous one. In this way a line of a heading is built up, and can be either straight or curved or disposed in any other way.

The sensitive material may be an ordinary photographic film which is then processed and serves as a basis for making a letterpress block or photo-litho plate.

Alternatively special films may be used incorporating a developing agent in the emulsion. Before the setting operation the film is soaked in an alkaline activator, and laid on the easel. After every exposure of a letter the latter then develops up instantly, and is visible as the next letter is projected into place. This simplifies visual alignment and layout. When the display is complete, the film is fixed and used for block or plate making. R.W.D. (F.H.S.)

pH VALUE. Number signifying alkalinity on a logarithmic scale. It is the negative logarithm of the hydrogen ion concentration. Pure water, which is neutral, has a hydrogen ion concentration of 10^{-7}, and thus a pH value of 7. Values below 7 are acid and above are alkaline, as indicated in the table.

As the scale of pH values is logarithmic, each unit represents a degree of alkalinity which is ten times as strong as the next below, and one tenth as strong as the next above.

The chief importance of pH values in photography is their effect on the activity of developers. Most normal developing agents work with greatest efficiency in an alkaline solution. The degree of alkalinity and the way in which it is achieved (i.e., by small amounts of strong alkali, or large amounts of weak) have a decisive effect on the characteristics of the developer.

pH VALUES

pH-value	Solution is:
0– 2	strongly acid
3– 4	acid
5– 6	weakly acid
7	neutral (pure water)
8– 9	weakly alkaline
10–11	alkaline
12–14	strongly alkaline

Various ways are used to determine the pH of a solution directly. The main methods measure the potential of a glass, hydrogen, or quinhydrone electrode when immersed in the solution under examination. These are usually incorporated in so-called pH meters, and give a direct reading of pH on a scale of a voltmeter.

In visual pH meters the colour of a universal indicator mixture added to the solution is compared with standard hues of the indicator at known pH values.

See also: *Indicator chemicals.*

PHYSICAL DEVELOPMENT.—In physical development, most of the silver forming the negative image is supplied by the developer and not by the emulsion as in normal development. A physical developer usually consists of a solution of silver nitrate with sodium sulphite, a silver solvent like sodium thiosulphate, and a certain amount of normal developing agent added.

The main reason for the developing agent is that there must be a weak silver image there before physical development can start. The initial silver image is intensified by the addition of silver deposited on it from the solution. The process is therefore a modified form of silver intensification.

The proportions of silver nitrate and developer must be carefully balanced to achieve a suitable rate of silver deposition without fog, and for this reason the chemicals have to be weighed out even more accurately, and clean work is more important, than usual.

Image Characteristics. As very little of the silver halide in the emulsion is reduced, the image grain bears little relationship to the graininess of the emulsion. The grain obtained is, in fact, very fine, and subsequent silver deposition does not materially increase it. And as the image consists of a deposit of silver on the surface of the emulsion, it has very little thickness, so its resolution is also very good.

A certain amount of physical development occurs in the solvent fine grain developers. But its extent, compared with the normal chemical development taking place at the same time, is very much smaller.

Ingredients of Physical Developers. Physical developers can be either acid or alkaline. While the alkaline formulae are more stable, the acid ones act more rapidly.

The silver nitrate is the main constituent of the physical developer. It supplies the silver to build up the image.

The sodium sulphite and the thiosulphate form soluble silver compounds which are not precipitated by the alkali of the developer.

The sodium thiosulphate also dissolves away the silver salts in the emulsion, and puts an early end to the initial chemical development. This, however, reduces the effective photographic speed of the material and since there has to be a fairly high concentration of thiosulphate (about 3–4 per cent), this loss of speed cannot be avoided by reducing the hypo content of the solution.

But the action of the thiosulphate on the silver salts in the emulsion can be slowed down by converting the silver bromide in the emulsion into silver iodide which is much less soluble

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

in thiosulphate solutions. To do this, the film or plate is treated in a forebath of potassium iodide. A thorough rinse between this forebath and the actual developer is essential to prevent precipitation of insoluble silver iodide by potassium iodide carried over.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Almost any developing agent can be used, but metol, or metol and hydroquinone give the cleanest results.

Development Time. The exact amount of developing agent present controls the rate of development. This is greatly affected by even small changes of concentration and it is useful to be able to check the activity before actually using the developer. A check of this sort can be made in the following way.

The actual time of development for any particular negative is first found by experiment, i.e., by developing strips of exposed film for varying times, and comparing them. At the same time, one drop of the same lot of developer is placed on a piece of contact or bromide paper, well fogged by exposure to light. After a short time the paper discolours and turns yellow or pink where the drop of developer was placed.

The time it takes for the paper to change colour is always in a fixed ratio to the development time of the particular film or plate. If, for instance, the spot takes 1 minute to appear, and the best development time for the film in question was found to be 15 minutes, this ratio is 15 : 1. If with another batch of developer the spot takes 1 minute and 20 seconds to change colour, then the same film would have to be developed for 20 minutes to obtain the same result. This relationship only holds of course if the same negative material and the same printing paper are used in both cases. The ratio must be found by trial every time the negative material or test paper is changed.

The development speed for physical development does not follow the same rules as in a normal developer. So it is not possible to estimate the correct development time of various negative materials in a physical developer simply by knowing the relative development times in a normal developer.

But once the ratio of discoloration time to development time has been found for any one combination of negative material and printing paper, it will always be the same for those materials. So it can be used to find the correct time with a new lot of developer.

Formulae. The following formulae are for a physical developer forebath and for solutions A and B of a physical developer.

Forebath				
Sodium sulphite, anhydrous	1	ounce	25	grams
Potassium iodide	175	grains	10	grams
Water to make	40	ounces	1,000	c.cm.
Solution A				
Sodium sulphite, anhydrous	2	ounces	50	grams
Silver nitrate	1¼	ounces	32	grams
Sodium thiosulphate (hypo)	6	ounces	150	grams
Distilled water to make	40	ounces	1,000	c.cm.

First, the silver nitrate is dissolved in about 8 ounces (200 c.cm.) of water. Then the sodium sulphite, dissolved in about 20 ounces (500 c.cm.), is slowly stirred in. When the precipitate which is first formed has redissolved, the thiosulphate is added. Finally, the rest of the water is added to make the correct volume. The solution will keep almost indefinitely.

Solution B				
Metol	35	grains	2	grams
Sodium sulphite, anhydrous	175	grains	10	grams
Hydroquinone	60	grains	3·4	grams
Sodium hydroxide	60	grains	3·4	grams
Distilled water to make	4	ounces	100	c.cm.

Procedure. The film is first immersed in the forebath for 1½ minutes. It is then rinsed well, and transferred to the working developer. This consists of 10 parts A, 1 part B, and 40 parts water; it must be made up immediately before use, and thrown away afterwards. Development takes about 25–30 minutes at 65°F. (18·4°C.).

The film is fixed in an acid fixer containing at least 30 per cent sodium thiosulphate. This may take well over an hour, since the silver iodide dissolves very slowly. Washing also should take at least an hour.

A formalin hardener (1 part formalin solution to 80 parts water) can be used at any stage; the best time is probably between development and fixing.

The film may be milky because of a fine deposit of silver (not to be confused with the milkiness due to incomplete fixation). This can be cleared by a brief immersion in a 0·1 per cent potassium bichromate solution containing 0·2 per cent sulphuric acid. Too long treatment in this bath will, however, affect the image. The same solution, but made 25 times stronger, will remove any silver deposit from the tank, etc.

If the film is found to be under-developed, it can be put into a freshly made solution of the developer again (even after fixing) and the development (which is now pure silver intensification) will continue normally.

Silver solutions stain the skin black so it is wise to wear rubber gloves when handling physical developers. L.A.M.

PHYSICAL REDUCTION. Methods of reducing the density of the silver deposit forming the photographic image by scraping or abrasion.

See also: *Retouching.*

PHYSIOGRAM. Pattern recorded photographically by a point of light attached to a swinging pendulum. The pattern possesses an unusual and delicate beauty and is capable of endless variations.

Making a Physiogram. This is not as complicated as the name might suggest. Beyond a camera, all that is needed is an electric torch without its reflector, and a piece of string to act

as a pendulum. The physiogram is made by photographing the track of the torch bulb on the film as it swings on the end of the pendulum which is suspended in a darkened room.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The camera is laid on the floor with the lens pointing upwards so that the torch bulb is directly over the centre of the lens. A lens cap is placed over the lens and the shutter opened on a time exposure. The pendulum is set swinging and when it has steadied itself and the torch has stopped wobbling from the momentum of the swing, the lens cap is removed and the exposure is allowed to continue for a period depending on the effect aimed at.

Varying methods of suspension give rise to different patterns. If the pendulum is made with a single string, the result will be a pattern of ever-diminishing circles or ellipses. If a V shaped pendulum is used, the pendulum proper beginning at the point of the V, about a foot from the ceiling, the pendulum will swing in two movements, one diagonal to the other. Its second movement cuts directly across the first, and the third across the second, and so on until the pendulum comes to a standstill. The result will be either a square or oblong pattern.

If the pendulum is hung by three strings instead of two, the arcs of the pendulum will cut across each other three times instead of two, resulting in another type of physiogram. More strings can be added, each extra string adding variety to the pattern.

Another variation in the suspension of the pendulum can be made by tying the third string from the point of the V to the end of a piece of spring steel attached to the ceiling. This causes the action of the pendulum to last longer and introduces interesting variations to the swing. Other methods of suspension can be developed from the methods described. By giving the pendulum an oval or a circular swing, it will again vary the design of the resulting pattern.

The results of these patterns do not depend on the skill of the photographer. Novices and advanced workers have an equal chance.

With a fast film the aperture should be about *f* 11. The exact exposure can be calculated after several tests.

Colour Physiograms. When making physiograms in colour, the film should be of the artificial light type. The simplest way to produce colour is just to use a coloured torch bulb, but this does not take advantage of the range of colours of which the film is capable. Two or more bulbs of various colours can be suspended together to increase the colour range. Alternatively, multiple exposures can be made with single bulbs of different colours.

A greater range of colours can be had by using filters over the lens instead of coloured bulbs. A selection of filters of equal density can be held alternatively over the lens while the pendulum is swinging. A good idea is to make a graduated colour filter by painting the full spectrum with coloured dyes on a circle of blank sheet film; the colours must, however, be applied evenly. One side of the film is rotated over the lens during the exposure. This causes the pattern to record in continuously changing colours.

PICTORIAL HISTORY. The development of pictorial photography has progressed along definable lines. In the earliest stages they were conditioned by technical limitations primarily, but later other factors also became significant.

See also: *Discovery of photography; Painting and photography; Pictorialism.*

PICTORIALISM. Method of photographic representation which aims primarily at aesthetic, emotional and intellectual effects. Design and tone rendering in a pictorial photograph are considered and controlled in such a way as to reinforce or create some appeal of their own which may or may not be inherent in the subject. Pictorialists are less concerned with the subject than with the picture it will yield; they use their cameras not so much to record whatever is there but to stress how they see. Thus pictorialism may be defined as a form of self-expression using the tool of photography with the object of creating images for the sake of enjoying both the process and the product.

In popular controversy the term pictorialism has come to stand for old-fashioned and sentimental conceptions of picture making. Some old-fashioned, sentimental photography may be pictorialism but not all pictorialism is old-fashioned and sentimental. The description pictorialism is too often used arbitrarily; people will never agree about it any more than they will about that other abstraction, "Art".

Past. What is now called pictorialism originated in the late nineteenth century, but the attempt to prove that photography was a medium capable of producing art started in the mid-1850s, and was then called High-Art photography. The term pictorial was chosen as a synonym for artistic photography. In these circumstances it was natural for pictorial photography to follow the subjects and the styles favoured by recognized forms of art as represented in the schools which were then most admired. This is why the most frequently cited pictorial photographs of the 1890's and the early 1900's sometimes resemble paintings, drawings and engravings of the impressionist era. To achieve this resemblance and at the same time broaden the limited tone rendering which the sensitized materials of their

day would afford, pictorial photographers initiated and made use of a great variety of controlled printing processes, some of them so ingenious that their products eventually succeeded in approximating to the appearance of hand-made works of art and left little to reveal that they originated in a camera.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The interests and conventions of the early pictorialists remained to some extent preserved through exhibitions and salons which, again following the examples of older arts, were chosen as the chief media for drawing attention to the artistic aspirations of photographers. Their inclination to conserve traditional standards has been reinforced by an increasing isolation from newer trends whose exponents looked for alternative outlets to the public, e.g., in the growing number of illustrated journals. Thus there are frequent and mutual complaints that exhibiting pictorialists will only repeat effects that have degenerated into clichés and those who have anything new to show stubbornly refuse to exhibit.

Pictorialism, started as a controversial gesture, has remained controversial ever since. As it deals in intangible and elusive values it is always equally easy to attack or defend. In addition, its nature and function are often misrepresented by those who identify the term with ideas handed down by and confined to a definite period of photographic history. Yet essentially any photography that puts the picture first and the subject second—that is any photography for the sake of photography—is pictorialism, and that includes the most advanced trends of modern photography as well. Any photograph that neglects or plays down the identity of its subject in order to stress atmosphere, mood, pattern or viewpoint, stands for pictorialism irrespective of its style, period or ideology.

Present. Most present-day pictorialism favours close approach, angled viewpoints, dramatized lighting, emphatic tone rendering, simplified shapes and a variety of associated appeals: it is a blend of the traditions of the exhibition and the salon with modern ideas that have seeped in from illustrative and commercial photography. But trends like these never last long and do not hold the stage by themselves even while they last. What was taboo some years ago and seems only eccentric to-day may become popular next year and yet hopelessly old-fashioned a little later. As with music, the really popular ideas are quickly worked to death while the merit of highbrow experiments takes a long time to sort out and assess.

The dominant qualities of pictorial photography have always been technical perfectionism, deliberate composition and a conscious search for artistic expression. If efforts of this kind are to convey an element of spontaneity and leave a lasting impression they must be based on original vision, subtle craftmanship and sincerity. Lacking creative powers of a high enough order, the pictorialist will be tempted to repeat ideas, patterns and methods originated by others and thus produce clichés. But clichés are not confined to any trend. They simply become more and more frequent as any theme grows older and its scope for variation is gradually exhausted. The pictorialist of to-day would not dream of trying to express anything original in the romantic vein of the school acclaimed a hundred years ago and exemplified by Henry Peach Robinson. Neither is there anything more to add to the atmospheric moods conveyed by the rich prints of sixty years standing produced, for example, by Alexander Keighley, although a few pictorialists may continue to copy his style. The texture-conscious naturalism of thirty-five years ago, represented at its best by Edward Weston, is still modern to many and may occasionally yield some photographic glimpse which is new. What you may seek to pictorialize with your camera and how you do it very much depends upon when you came in to photography, and where.

Whatever trend he may follow the pictorialist is restricted by his self-chosen philosophy of recognizing the supremacy of manner over matter. But although the subject of photography is as endless as the world, its modes of expression are confined to specific and narrow techniques. Paradoxically pictorial progress directly depends on technical progress.

Scope. Photographic pictorialism being a means of self-expression needs to fulfil no other function beyond leaving the photographer contented with his work—particularly if he is an amateur. He is entitled to derive all the satisfaction he may be able to gain by using his camera to capture his own particular day-dreams irrespective of whether these add up to chocolate box prettiness, visions of social discord or surrealistic humour. It is also immaterial whether what he creates is of any interest to others besides himself. Approval or disapproval are of secondary importance to the pictorialist; his work does not depend on a public. The extensive and ecstatic vocabulary that has been used around pictorial photography is but a social game that gives the participants a chance to clothe their personal likes and dislikes in more or less profound statements. These, however much they may analyse the trends of the past or argue about the present, settle nothing for the future. A glance at any dogmatic assertion on pictorialism made twenty, thirty or forty years ago is enough to show how futile specific rules and theories are in this field. Pictorial photography remains free for all.

Photographic pictorialism as a contribution to progress, however, is effective only at the infrequent stages when from time to time new techniques yield novel methods of expression that may fertilize other arts or, more generally, may be borrowed by other photographers who

care less about the tool they use and more about the things it can be used for. Sometimes, and by no means in its worst examples, pictorialism appears as sheer sublimated technique. Being so little concerned with subject matter and so much with modes of presentation, pictorialism is free to play virtuoso exercises throughout the whole range of photographic expression.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Pictorialism is photographic art for art's sake; mostly pleasant, sometimes admirable but hardly ever the end in itself it imagines itself to be. The image will always recall its original and any photograph, however successfully pictorial, leaves the onlooker wondering, in some measure, just who the person or where the place or what the thing is at which the lens was looking. No photographic subject will ever wholly submerge in photographic manner. The traditional pictorialist's affectation in suppressing the identity of the subjects behind some wistful, poetic or highbrow caption only interferes with the appreciation of his work and may even irritate the man who looks at it. The natural, popular and effectual photograph will always be the one that has been taken simply to show and to identify something or somebody. Pictorialism is a forced growth out of the main body of photography; a hot-house plant perhaps, but no less delightful for that. Being the product of the creative urge it has its own dignity as a human document. Even if it should not record the realities of its time it still does reflect on them by its very evasions. What a man may dream about is often more important than what he does or says when he is very much awake. A.K.-K.

PICTURE SERIES. Number of pictures built around a single narrative or theme. Picture series have many forms, from such carefully studied and planned sequences as a documentation of a place to the random, spontaneous sequences such as a street riot would provide. Only a relatively few specialists have succeeded in mastering the artistic as well as the technica requirements of the photo-story.

Requirements. Some training in journalism is an asset in this branch of photography. There must be a strong and obvious story; each photograph must convey its own message clearly; captions are used only for information that cannot be expressed in the picture. The most successful picture series is one in which the photographs tell the greatest possible proportion of the story without assistance from the text, always providing that the subject has interest and the treatment is alive and exciting.

Construction. The photographer, with the main idea for a picture series in mind, collects all the relevant facts and looks for the natural sequence either in time or action. Then he looks for possible "highlight" pictures. These are essential to the interest of the series and should in fact be good enough to stand alone. One of these must be an outstandingly good shot which concentrates the whole idea into one picture either for use on the magazine cover, or to dominate the layout of the series.

Presentation. The photographer must also work to produce an interesting page layout, and for this reason he should know something of magazine make-up. A series is apt to look uninteresting if all the shots are taken from the same distance and angle. So close-up and long shots are combined to add variety. Absolute familiarity with the equipment and technical routine is essential so that the photographer is free to give his attention to the story content. And the final series must be more than a mere factual record; it must carry the stamp of the observer's personality in its selection of the critical instants and in its appreciation of the dramatic possibilities of the subject. This essential personal quality comes through more clearly when the picture shows only the significant thing and leaves out everything else.

Selection. A picture series is seldom a record of a single sequence of events made in six or eight consecutive exposures. The action may have to be repeated many times before the photographer gets all the pictures he wants. He takes many more steps in the sequence than he is likely to need, and sometimes photographs each step from a number of different angles and positions.

Most magazine picture stories of about half a dozen pictures are the result of making upwards of a hundred separate exposures and selecting those which express the idea most clearly, and make the most arresting pictures.

Camera. The range of the equipment governs the subjects that can be tackled. A photographer who wishes to specialize in this branch of photography should be able to command a first-class miniature with wide-angle and long-focus lenses, at least one lens with an aperture of *f*2 or larger, and a twin lens reflex. The miniature camera would ideally be a single-lens reflex, and at least one of the cameras should be fully synchronized for flash.

In addition, a 5 × 4 ins. or 9 × 12 cm. camera for colour is almost essential to anyone working for the magazines.

Lighting. Wherever possible the existing lighting is used so that the subject and its surroundings will look natural. If the existing lighting does not allow for the necessary shutter speed and depth of field, then Photoflood lighting is commonly used. This is satisfactory so long as there is no fast action, and it is more economical than the use of flash bulbs where a large number of exposures has to be made. Where the speed of the action or an outdoor night scene rules out Photoflood lighting, then flash must be used. A bulb above and to the side of the camera sight line and a fill-in flash

on the camera give a sufficiently natural effect.

Electronic flash is the most satisfactory light ing for very fast action pictures in bad light.

Ideally all technical manipulations and considerations should become almost second nature, allowing the photographer to concentrate solely on his story. M.A.

PIEZO-ELECTRIC FLASH. Flash bulb fired by the current derived from a mechanical shock or stress on certain types of crystals. The so-called piezo-electric current produced in this way (similar in principle to the current produced by a crystal microphone) is very small, and can fire only flash bulbs specially designed for this purpose. A piezo-electric system of flash synchronization has, however, the advantage that it is very compact, and does not have to rely on batteries.

See also: *Flash bulbs.*

PIGEON POST. During the Siege of Paris 1870–71, greatly reduced photographs of printed messages on collodion pellicles $1\frac{3}{4} \times 2\frac{3}{8}$ ins. were carried by pigeons from the headquarters of the Government to the besieged capital. There they were projected, copied by clerks and delivered to the addressees. Eventually the messages were printed on photographic paper. This pigeon post was a forerunner of the airgraphs of World War II.

See also: *Dagron.*

PIGMENT PROCESSES. Methods of making positive prints by exploiting the various physical changes produced in a bichromated colloid by the action of light. Certain organic colloids—e.g., albumen, casein, gelatin, gum arabic and shellac—and a few cellulose and polyvinyl esters, sensitized with a bichromate—e.g., of potassium, ammonium or pyridine—change their physical character when exposed to light.

Three principal changes may take place in the colloid: if previously soluble it may become insoluble; it may no longer absorb water and swell up; it may lose its surface tackiness.

The principal processes based on the change in solubility of the colloid are Artigue's process, and the carbon, carbro, Fresson, gelatin-sugar and gum bichromate processes. Here the broad principle is that a pigmented layer of bichromated colloid is exposed under a negative and subsequently developed by washing with hot water which dissolves the unexposed colloid and leaves a positive image consisting of pigment suspended in the exposed and insoluble colloid.

The principal processes based on the swelling of the colloid are bromoil, oil printing and dye imbibition. In these the layer of colloid after exposure under a negative is bathed with water so that the unexposed areas swel. and become water-logged. Greasy ink which is then applied with a brush is rejected by the swollen areas and accepted by the exposed unswollen colloid to form an image. Various dye imbibition processes are based on the permeability of the colloid to an aqueous solution. In these, the colloid layer after exposure is bathed in a dye solution which it absorbs in the unexposed areas to give a positive-from-positive image.

The principal process based on loss of tackiness is the dusting-on or powder process. In this a bichromated colloid—e.g., gum arabic—is exposed and "developed" by being lightly brushed over with a finely powdered pigment. Where the light has acted, the surface loses its tackiness and the pigment does not adhere. So an image is formed on the tacky, unexposed areas.

The process gives a positive image from a positive transparency. A positive can be printed from a negative by coating the colloid on a dark support and developing it with a light powder.

See also: *Control processes; Printing processes (obsolete).*

PINACHROME PROCESS. An obsolete colour printing process based upon the use of leuco bases which oxidize on exposure to light, yielding colour images. Three such colour images, derived for instance from separation negatives, can be assembled by superposition.

PINACRYPTOL. Used in desensitizers.

Characteristics: Green (pinacryptol green) and yellow (pinacryptol yellow) dye powders.

Solubility: Slightly soluble in water. Soluble in alcohol.

PINATYPE PROCESS. A method for producing dye imbibition colour photographic prints based on the differential staining action of certain dyes for hard and soft gelatin.

See also: *Printing processes (obsolete).*

PINCUSHION DISTORTION. Particular kind of optical distortion of the image formed by an uncorrected lens. Straight, parallel lines at the edge of the field curve towards the lens axis being closer at their middle than at the ends.

See also: *Aberrations of lenses.*

PINHOLE CAMERA. Photographic camera without a lens but instead with a very small, sharp-edged hole in an opaque diaphragm. Such a hole forms an image at the back of the camera, varying in scale and perspective according to the distance between the diaphragm and the sensitive surface. If the pinhole is close to the plate it gives a wide-angle lens effect; if it is far away it gives a picture equivalent to a long-focus lens.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Image Quality. The quality of the pinhole image depends on the size and sharpness of the hole. Up to a point, the quality improves as the hole is made smaller, but beyond a certain size it deteriorates because diffraction becomes more pronounced.

The definition produced by the pinhole camera is determined by the size of the image patch corresponding to a point object. The diameter of the image patch formed by rays of light from a point source is given by

$$D = \frac{d(u + v)}{u}$$

where D = diameter of the image patch,
d = diameter of the pinhole
where u = distance of the object from the pinhole,
v = distance of the image from the pinhole.

So, if u is large compared with v, even a large pinhole will give a reasonably sharp image. For instance, a keyhole will give a recognizable picture in a darkened room of buildings more than one hundred feet away.

Size of Hole. There is an optimum—though by no means critical—size of hole for any particular hole-to-plate distance. While a lot of theoretical work has been done on this subject and many formulae have been published, for practical purposes it is sufficient to approximate very roughly. A pinhole of about 1/64 in. diameter is satisfactory for normal photography with separations up to 6 ins., and 1/100 in. will give reasonable definition for copying and photographing small objects on a scale of 1 : 1.

Making the Hole. The pinhole itself is worth taking trouble over. It should be a clean, sharp-edged hole with as little depth as possible.

Take a piece of brass about 1/32 in. thick and cut it to form a blank to fit in place of the camera lens. Tap a dimple in the centre of the blank with a blunt-ended centre punch and rub the point of the dimple down with a dead smooth file to form a thin place.

Pierce the thin spot with a sewing needle of suitable diameter, working from the hollow side of the dimple. Carefully rub off the burr with a fine flat carborundum stone and pass the needle through the hole again. Rub off until the hole is seen to be clean and sharp when looked at through a watchmaker's glass. Finally blacken the metal and the pinhole will be ready for use.

Exposures. The exposure depends upon the size of the pinhole and its distance from the plate—in other words, its *f*-value. And the *f*-value can be calculated exactly as for a lens, although it will vary for each hole-to-plate distance. A 1/64 in. pinhole working at 6 ins. from the plate, for instance, will have an *f*-value of

$$\frac{6 \times 64}{1} = f384.$$

Under these conditions, when the light would normally call for an exposure of, say, 1/25 at *f* 11, the exposure time would be 49 seconds.

As there is no need for accuracy with such long exposures, a safe working rule with this pinhole and distance would be to reckon at the rate of one minute of exposure for every 1/25 second of exposure at *f*8 given by the meter. In the same way a rule of thumb can be worked out for any hole and distance by making one representative calculation.

The Photograph. Pinhole photographs have an all-over softness of definition which is substantially the same for all objects in front of the camera. There is no distortion, and the depth of field extends from the front of the camera to the horizon. Finally the photographer has absolute freedom to vary the perspective of his subject and the scale of reproduction by altering the relative distances of the plate and the subject from the pinhole.

The disadvantages of the pinhole photograph are mainly the lack of crisp definition, the length of the exposure, and the alteration of the "*f*-value" with every change of plate distance.

F.P.

PINHOLES. Clear, small spots in the negative caused generally by specks of dust on the emulsion surface at the time of exposure.

See also: *Faults; Spots.*

PIN-UP. (Slang.) Glamorized photograph of a motion picture or stage beauty almost always taken in a bathing suit or lingerie. So called because this type of picture is commonly given away in the form of an insert in a popular magazine so that it can be pinned up as a decoration.

PIPER, C. WELBORNE, 1866–1919. English photographer. Introduced the bromoil process in 1907 as a result of a suggestion by E. J. Wall.

PIX. (Slang.) Abbreviated phonetic for pictures, coined originally—and still mainly employed—in America for its convenience in making up newspaper headlines.

PIZZIGHELLI, GIUSEPPE, 1849–1912. Austrian officer and photographic scientist of Italian origin. From 1878–1884 head of the photographic department of the Army, Vienna. Later president of the Società Fotografica Italiana (Italian Photographic Society). Collaborated with J. M. Eder, notably in the production of silver chloride ammonia emulsions for development papers, 1880–1; this antedated Baekeland's commercial introduction of Velox paper by 12 years. Improved, with von Hubl, Willis' Platinotype process and discovered in 1887 the platinum printing-out process in which no further development is required after printing.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PLANOGRAPHIC PROCESSES. Printing processes in which the printing and non-printing areas of the plate are all at the same level (e.g., in lithography).

See also: *Photomechanical reproduction.*

PLANTS. Photography is used extensively by naturalists and botanists for recording plant growth and characteristics both in the field and in the laboratory.

See also: *Biology; Botany; Flowers; Garden.*

PLASTICS. Organic compounds usually formed by the chemical reaction known as polymerization which combines comparatively simple molecules into long chain structures. The resulting substances are comparatively tough (though not necessarily hard) solids of fairly good strength, chemical resistance and easy workability. The latter property makes them particularly valuable for the manufacture for a wide range of objects and articles of all kinds.

Polymerization can often be induced by light, or a polymer may be cross-linked by a light-catalyzed reaction and these effects are of importance in photography. Further, the physical properties of certain plastics make them suitable for use both as film supports and as material for the manufacture of processing and other equipment.

Photosensitive Plastics. A high polymer is said to be light-sensitive if, after exposure to a suitable light source, the exposed area of a film or coating of the polymer is distinguishable from the unexposed area, either with or without some development step. Among early polymeric materials used in this way was bitumen, which was employed in the original photographic process of Nièpce (1829). Gelatin and albumen sensitized with dichromates have long found application in screen printing and photomechanical work, though they are not strictly speaking plastics.

Synthetic and natural polymers can be made light-sensitive essentially in two ways: (a) the light-sensitive component can be an integral part of the polymer molecule and (b) a substance which may react with a polymer molecule or may photopolymerize itself on exposure to light, in the presence of a light sensitive activator, can be added to the normally non-light-sensitive polymer.

Variations of (b) are known where the addition of only a small amount of a light-sensitive material will bring about a light-induced chemical reaction in the polymer.

Among group (a) systems, polymers containing anthracene or cinnamate residues have been prominent. When a coating containing a polymer having such groups built into the molecule is exposed to light, some of the cinnamate or anthracene groups in one molecule will combine with a similar group in another molecule, producing a change in the physical properties of the molecule. The image can be developed by washing out the unexposed areas with a suitable solvent in which the exposed areas are insoluble. Such an image can be dyed.

The polymers are usually sensitive to ultraviolet rays only, but they can be spectrally sensitized.

Several processes falling into type (b) are known. A doubly ethylenically-unsaturated compound may be added to a large variety of plastic materials ranging from nylon to polyesters and cellulose derivatives. In this case, the further addition of a light-sensitive activator is required. Diesters of acrylic acid and various glycols have been suggested as the unsaturated material and ketones such as biacetyl, benzoin and benzil are the activators. On exposure to light, the unsaturated compounds crosslink the plastic and render it soluble in a given solvent system.

In other processes azides have been used as light-sensitive crosslinking agents. Here also a large variety of high polymers have been used, including proteins, e.g., gelatin and casein, and materials like nylon, rubber and rubber derivatives.

The applications of the various light-sensitive plastic materials are increasing rapidly. They are especially useful in the electronics industry, in the production of printed circuits and various macro- and micro-solid state devices, in the manufacture of name-plates, in chemical milling and etching of engineering components, the production of decorative designs, decorative ceramics, tricolour television phosphor screens and in the engraving of textile-printing rollers. Electrodeposition into a photographic resist image makes use of the high dielectric value of the photosensitive plastic. Letterpress printing plates made of light-sensitive plastic materials have appeared on the market.

Plastic materials can also be used in electrostatic processes similar to xerography. Polymers containing photoconductive groups have been patented. Among the most prominent of these have been polymers containing carbazole and polynuclear hydrocarbons. H.M.W.

Film Bases. Virtually all transparent emulsion supports other than glass are polymer plastics of one kind or another. Before the turn of the century, cellulose nitrate was used as the first flexible transparent film base. This material had many excellent mechanical properties although it was extremely flammable and was not chemically stable.

Nevertheless, it continued to be used as late as the 1950's.

To overcome the poor flammability and stability characteristics of cellulose nitrate, cellulose diacetate was introduced in the early 1920's. However, this material did not have as good mechanical properties as cellulose nitrate and is not widely used today. In the 1930's, film

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

bases composed of mixed cellulose esters were introduced. These cellulose acetate propionate and cellulose acetate butyrate bases had improved physical properties and are currently used for many sheet and amateur films. During this period, cellulose triacetate base was developed and this came into widespread use after World War II. It has excellent strength, toughness, and burning properties and is most desirable for professional motion-picture films. It is currently being used for the majority of photographic films.

Cellulosic film supports do not have the dimensional stability properties desired in some applications, primarily in the graphic arts industry. For this purpose, rigid polyvinyl chloride-acetate base was introduced in the 1940's. While it has low moisture adsorption, it was translucent and had a low softening temperature. It never attained widespread use. In 1954, a biaxially-oriented polystyrene base was marketed and it had wide acceptance because of its excellent moisture resistance. Its mechanical properties were not high and it showed craze marks if kinked. It has been supplanted to a considerable extent by biascially-oriented polyethyene terephthalate base. which is a polyester. This material has excellent dimensional stability combined with mechanical strength which is superior to any other film base. For this reason it has found use not only as a base for graphic arts films, but also for aerial and industrial films. Another widely used polyester type film base is polycarbonate with good moisture resistance. It has been used for graphic arts and for aerial films.

Processing Equipment. The use of plastics in processing equipment is dependent upon both their chemical and mechanical suitability. The former includes both the effects that the processing solutions may have on the plastic such as swelling or plasticizer leaching, as well as any photographic activity of the plastic.

Polyacrylonitrile-butadiene-styrene, cellulose acetate butyrate, polyethylene, polypropylene, and rigid polyvinyl chloride find application as fittings, piping, trays, paddles and tanks. The fluorocarbon polymers are found in pumps, gaskets, packings, bearings and small parts. Nylon has been suitable for gears and bearings, and polystyrene, polyoxymethylene and reinforced phenol-formaldehyde resins for small parts. Epoxys and urethanes are also coated onto metals and employed for film hangers, racks, idler rolls and tanks. Large tanks and other equipment are also constructed from fibreglass reinforced epoxys and polyesters.

This review of plastic usage is a generalization based on trade experience. However, there are considerable variations within any one plastic as to its suitability, as well as wide variations between different photographic processes. P.Z.A.

See also: *Photo-etching; Resist; Supports for emulsions; Tanks.*

PLATE. Photographic material formed by coating a sensitized emulsion on to a sheet of glass. Plates are carried in wood or metal plate holders fitted with a removable draw slide which shields the sensitive surface from the light until the plate is to be exposed in the camera.

See also: *Negative materials; Supports for emulsions; Transparency materials.*

PLATEAU, JOSEPH ANTOINE FERDINAND, 1801–83. Belgian physicist, specializing in optics. Discovered in 1829 the principle of the "wheel of life" which he constructed in 1832 under the name Phenakistiscope; it was discovered simultaneously by Stampfer in Vienna who called his instrument the Stroboscope. Proposed the use of instantaneous photographs (instead of hand drawings of motion series) in 1849; this was attempted in 1851 by Claudet and Duboscq, and later by Uchatius, Muybridge, Marey, Demeny and others.

PLATE CAMERA. Camera designed primarily to take photographs on coated glass plates. The back of a plate camera is equipped to take either the plate in its light-tight holder or sheath, or a focusing screen. The ground surface of the screen and the surface of the plate lie in the same plane when they are in position. The photographer focuses and arranges the subject on the screen and then substitutes the plate in its holder. So long as the subject or camera does not move in the meantime, the image on the plate on exposure will be identical.

Plate cameras are particularly suitable for making single exposures that can be removed and processed at once, unlike roll films which must be all exposed before any can be seen. Plate cameras are generally larger than film cameras and tend to be used mostly by professional photographers.

Although the plate camera is, traditionally, an old type of camera, there are many modern versions designed for specific purposes and the use of sheet film material is today more common than the use of plates in such cameras. It has decided advantages, particularly where great accuracy is important.

Some of the smaller and miniature roll and 35 mm. cameras can be fitted with plate backs to enable them to take single exposures.

See also: *Field camera; Press camera; Technical camera.*

PLATE HOLDER. The sensitized plates used in plate cameras are held in readiness for use in light-tight containers called plate holders. A plate holder is simply a rectangular frame in which the plate is kept in place by some form of clip or slot. The back of the frame is solid and the front is open, but light is normally prevented from reaching the plate by an opaque dark slide. The slide can be withdrawn when the holder is in position on the camera.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The plate holder is designed to fit on the back of the camera in place of the focusing screen so that the sensitized surface lies in the same plane as the ground glass surface of the focusing screen.

There are various ways of attaching the plate holder to the back of the camera. The simplest—and worst—method is for the back of the camera to be grooved to allow either the focusing screen or a plate holder to be slid into place. With this method there is always a risk that the camera will be moved out of adjustment while withdrawing the focusing screen or inserting the plate holder. There is much less risk of movement when the plate holder is designed to clip into position with only a limited sliding action or none at all.

Plate holders are made in single and double form and in either metal or wood.

Single Holders. Single metal holders are supplied mainly with hand cameras and in formats no larger than quarter plate. The draw slide of the single metal holder is a metal plate which is so thin that it can be removed completely to make the exposure without allowing light to leak past the velvet light trap.

Plates are kept in position in the single metal type of holder by a leaf spring along the bottom groove which presses the plate upwards so that the top edge lodges under a pair of metal lugs. To load or unload a plate, it is simply pressed down against the spring pressure until the top edge clears the lugs after which it can be inserted or removed at once.

Double Book Form Holders. This type of holder is mostly made of wood and used to be popular with professional workers, particularly for formats of half-plate and larger. The holder in this case is really two plate holders assembled back to back, hinged together at the bottom and held closed by one or more clips along the edges. Each side of the holder consists of a wooden draw slide and a thin wooden frame with its inner edges rebated to take the plate. A blackened sheet metal separator is held in place by tabs on one side. The separator carries a leaf spring that presses the plates firmly into their frames so that all parts of the plate being exposed are in the focal plane of the lens.

PLATE HOLDERS. Top: Single plate holder. Bottom: Double plate holder. A, dark slide. B, plate in groove. C, pressure spring. E, hinge; opens for loading.

A wooden draw slide for this type of holder has to be about 1/16 in. thick, and if it were completely withdrawn with the holder in place on the back of the camera, the slit left would be too wide for the velvet light trap to close. So the slide is prevented from coming right out by a stop. As it is inconvenient to have a slide sticking out from the camera during the exposure, slides of this type—particularly the larger sizes—usually have a flexible section at the bottom which allows the slide to be folded out of harm's way against the back of the camera. The flexible section consists of strips of wood glued on each side of a width of opaque fabric.

Loading. To load a double book form plate holder, the clips are released and the holder is opened, book fashion. The clips holding the separator are released and a plate is placed in the frame on the same side, emulsion down. The separator is clipped down over the back of the plate.

A second plate is now placed emulsion down in the frame on the other half of the holder. The first half of the holder, with its plate secured by the separator, is then closed down on the plate lying in the open frame, and the two halves are fastened together with the side clips. The holder is now loaded ready for use.

Another widely used type of double dark slide has a cover that fits along the bottom edge of the holder. When this cover is removed the plates can be slipped into position behind the dark slides. A slight variation of this type has at the bottom a separate hinged cover for each plate, which can be opened independently when the appropriate slide is partially withdrawn.

Single metal plate holders are loaded by pulling out the draw slide, pulling back the spring at the top edge, dropping in the plate (emulsion side up) and releasing the spring so as to hold the plate in place.

Plate Identification. Plate holders are usually numbered serially so that the photographer can keep a running record of the exposed plates. A white ivorine panel is sometimes inlaid on wooden slide holders so that brief memoranda may be written on in pencil and wiped off when the plate is changed. Metal plate holders usually have the number embossed on the top of the draw slide.

Safety to Actinic Light. Plate holders are normally kept away from the light as much as possible and are usually kept in their carrying case with the lid closed. Although they are safe to a certain amount of light, there is always a risk of some light leaking through the light trap or being reflected around the edge of a loosely fitting draw slide. When on the camera, the holders should be covered by the focusing cloth, especially when working outdoors in bright light.

Metal draw slides are safe against most kinds of radiation (except X-rays) but wooden, plastic, and xylonite slides are more or less transparent to infra-red light. For this reason, infra-red sensitized plates must be used only in all-metal holders. There is even some risk from the deep red rays in sunlight if panchromatic plates are left lying about in the open sun in wooden or plastic holders.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Cleanliness. As far as possible, plate holders should be kept away from dust; this traditional source of trouble is always easier to keep out than get out. If the case they are carried in is regularly brushed out and occasionally blown out, and the holders are wrapped in a clean cloth or a square of soft plastic when they are out of the case, they should come to no harm. At the same time, before every loading they should be blown or brushed out with the dark slides withdrawn. The special miniature hand blowers sold for cleaning cameras are useful for this job because they can be used to blow a jet of air right into the grooves and crevices of the holder.

The velvet along the edges of the light trap should be brushed up and the blower used to drive any dust particles out of the pile.

Before loading a plate, a wise precaution is to tap the edge of the plate gently against the work-bench. This removes both dust, and also any static electricity on the plate, which would attract dust.

All these precautions take extra time, but nothing like as much as is wasted in spotting the negative and retouching the print because dust was present during exposure. F.P.

See also: *Film transport; Mackenzie-Wishart envelopes.*

PLATE MARKING. Area embossed on a print or its mount. It imitates the depression of the picture below the border level produced by the pressure of the engraved or etched plate in certain types of art reproduction.

See also: *Embossing prints.*

PLATE RACK. Wooden rack used to hold plates on edge while drying, and to permit complete drainage and free access of air from all sides.

PLATINOTYPE. Contact printing process invented by W. Willis (1873), in which the image was formed of platinum. Due to the high cost of platinum it was succeeded by the palladiotype, which used palladium in place of platinum.

See also: *Printing processes (obsolete).*

PLATINUM CHLORIDE. Platinic chloride; platinum perchloride. Used in certain toners and sensitizers.

Formula and molecular weight: $PtCl_4.5H_2O$; 427.

Characteristics: Red crystals giving a yellow solution.

Solubility: Highly soluble in water.

PLAYERTYPE. Direct copy of a line original made by a now obsolete process invented in 1896 by J. Hart Player.

The original is placed face upwards under a printing light, and a sheet of sensitized paper is placed over it and exposed in contact with it, emulsion side down. A negative image is produced on developing the sensitized paper and this is used to give any number of positive prints by normal contact printing. This process is now used for copying documents (reflex copying).

See also: *Document copying.*

POINT SOURCE LAMP. Special type of arc lamp. In it the arc is struck between tungsten beads sealed into a glass envelope from which the air has been extracted. A small quantity of mercury in the bulb is heated when the lamp is switched on and forms a conducting vapour which carries the arc current. The arc heats up the tungsten until it becomes incandescent and emits a light similar in colour to a tungsten filament lamp but from a concentrated source.

Point source (e.g., Pointolite) lamps are used in projectors, spotlights, and enlargers. The apparatus must incorporate a resistor or transformer to provide a 10 volt supply to the arc.

The efficiency and power of this type of arc can be greatly increased by raising the vapour pressure and operating it at a higher current. The light source is similar to Photofloods in application.

There are various other types of concentrated arc lamps in which metallic electrodes are used instead of carbons—e.g., the zirconium concentrated arc in which the light is emitted by a thin film of molten zirconium. The outstanding characteristic of the zirconium lamp

POINT SOURCE LAMP. An arc is struck (either by means of a heated filament, or by a high-voltage pulse) between two beads of tungsten in an atmosphere of mercury vapour. The bulk of the light emanates from the positive electrode, while the mercury contributes little to the colour of the light. As this is produced by incandescent tungsten, it resembles that of a filament lamp in colour. The lamps are made in ratings from 30 to 1,000 candle powers for D.C. operation, and in a more limited range for A.C. use. The voltage drop across the electrodes is only about 10 volts; the optical efficiency due to its near-point source is thus complemented by a high electrical efficiency obtained through the high current density.

is the very small source from as little as 0·003 in. (0·085 mm.) for the 2 watt size to 0·059 in. (1·5 mm.) for the 100 watt size.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Modern low voltage projection lamps frequently have a very concentrated filament which acts virtually like a point source. Lamps of this kind are frequently used with a built-in (proximity) reflector or a special shaped, internally silvered, glass envelope that acts as a reflector. Such a reflector is thus very small, a development only possible with a virtual point source of light.

See also: *Carbon arc lamp; Discharge lamp; Zirconium lamp.*

POISONS

Various chemicals used in photography need special care in handling owing to their poisonous nature. The sale of some of these is governed by law. Substances controlled by the Pharmacy and Poisons Act, 1933, are set out in the Poisons List and are the only poisons for the purpose of the Act. There are other substances used in photographic processes which are either nauseous or which have some element of danger, but which are not officially classed as poisons.

Until 1851 there was no effective legislative control over the sale of poisons in Great Britain, and statistics showed an increasing number of deaths from poisoning. In 1865 a select committee reported that there was need for a bill to provide that only registered persons should sell certain poisons and it was from this beginning that the Pharmacy and Poisons Act, 1933, evolved.

Categories of Poisons. The Poison List is divided into two parts:

Part I—sold only by chemists (authorized seller of poisons).

Part II—sold by authorized seller of poisons and listed sellers of poisons (this list is kept by the local authority).

Poisons are also grouped into schedules, each schedule having specific regulations which are governed by the rules of the Act, but which do not cover photographic use, except in so far as they are referred to below. The first schedule covers the most dangerous poisons in the Poison List.

Under the Act, local authorities must keep a list of persons allowed to sell Part II poisons including particulars of the premises, and these people are known as listed sellers of Part II poisons. The form of application to become a listed seller can be obtained from the local authority and the fee payable is 7s. 6d. for the first year and 5s. per annum subsequently.

Poisons in Part I of the list and those substances containing Part II poisons in the first schedule of the rules can only be sold on registered premises and by or under the supervision of a qualified pharmacist. Other poisons in Part II of the list may be sold by listed sellers.

Part II poisons which are included in the first schedule may be sold by listed sellers only in the form specified against each in the fifth schedule.

The following three groups of photographic chemicals show the position of the photographic dealer in regard to the selling of chemicals under the regulations.

Group I. Poisons which may be sold by the photographic dealer when he has become a listed seller of poisons, are:

Ammonia (liquid).
Hydrochloric acid.
Nitric acid.
Sulphuric acid.
Potassium quadroxalate (Salts of Sorrel, Salts of Lemon).

The following may only be sold in the closed containers in which they are received by the dealer:

Hydrofluoric acid.
Formaldehyde.
Potassium hydroxide (Pot. caustic).
Packed toners containing metallic oxalates.
Sodium hydroxide (soda caustic).

Group II. Chemicals and solutions which can be sold by the photographic dealer without his becoming a listed seller are:

Ammonium oxalate.
Ammonium sulphocyanide.
Paraphenylenediamine and its salts for photographic purposes.
Potassium ferricyanide (red prussiate of potash).
Solutions of ammonia containing less than 5 per cent weight in weight (w/w) of ammonia (NH_3).
Solutions of formaldehyde containing less than 5 per cent w/w formaldehyde. (Photographic glazing and hardening solutions containing formaldehyde have been specially exempted from the provisions of the Act.)
Solutions of hydrochloric acid containing less than 9 per cent w/w of hydrogen chloride (HCl).
Solutions of nitric acid containing less than 9 per cent w/w nitric acid (HNO_3).
Solutions of potassium hydroxide or sodium hydroxide containing less than 12 per cent of potassium or sodium hydroxide respectively. (These cover concentrated developers of the paraminophenol and contrast type.)
Solutions of sulphuric acid containing less than 9 per cent w/w of sulphuric acid (H_2SO_4).

Group III. Poisons which the photographic dealer cannot sell unless he is a registered pharmacist (i.e., authorised seller), include:

Barium sulphide.
Cyanides.
Hydrocyanic acid.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Types of Poison	Description	Symptoms of Poisoning	Antidotes
Alkalis	Potassium hydroxide (Pot. caustic) Sodium hydroxide (Soda caustic) Liq. ammonia	Swelling of tongue and mouth	0·6 per cent solution of glacial acetic acid in water (dilute vinegar will do in an emergency)
*Iodine		Tightness about the throat	Ample emetic, plenty of arrow-root
Lead acetate and nitrate		Constriction in the throat and pit of stomach and stiffness in abdomen	Sodium sulphate or Epsom salts, emetic of zinc sulphate
Mercuric chloride		Acrid metallic taste, constriction and burning in throat and stomach. Nausea and vomiting	White and yolk of raw eggs mixed with milk. In emergency ordinary flour paste may be used
Mineral acids	Hydrochloric, nitric, sulphuric	Corrosion of windpipe and violent inflammation	Sodium bicarbonate or magnesium carbonate, or chalk; even the plaster of the room beaten in water
*Potassium bichromate		Irritant pain in stomach	Emetics and magnesia or chalk
Potassium cyanide		Insensibility, slow gasping respiration, dilated pupils, spasmodic closure of the jaws	No certain remedy, try mixture in water of equal parts of ferrous sulphate and sodium carbonate. Hot and cold douches
Potassium oxalate and oxalic acid		Hot burning sensation in throat and stomach, vomiting, cramps and numbness	Chalk, whiting or magnesia suspended in water. Plaster or mortar may be used in emergency
*Pyrogallic acid		Violent vomiting, collapse, fall in temperature	Emetic, plenty of air or oxygen, hot water on hands and feet

*These three substances are not poisons within the meaning of the Act, but are usually included in lists such as this where antidotes are given.

Lead acetate and nitrate.
Mercuric chloride (mercury bichloride, corrosive sublimate.)
Mercuric iodide.
Oxalic acid.
Para-nitrophenyl acetonitrile.
Potassium oxalate.
Schlippe's Salts (sodium sulphoantimoniate).

Buying Poisons. Poisons of Groups I and II can be bought and sold over the counter in the normal way. Special requirements apply to substances in the first schedule (which includes the Group III poisons listed above).

A substance in the first schedule can only be sold to a purchaser who is known by the seller (or by a pharmacist in the employ of the seller) to be a person to whom that particular poison may properly be sold. A person who wishes to buy a substance in the first schedule from a chemist, and who is not known to the chemist, may be supplied if he presents an appropriate certificate. This must be signed by a householder who is known to the chemist to be a "responsible person of good character". If the purchaser cannot obtain a certificate from a householder known to the chemist, he can obtain one from another householder and get the police of the district to endorse the certificate that the householder is known to the police to be a responsible person of good character.

When a person requires a substance in the first schedule for other purposes than his trade or business, he must also be known to the seller or be certified in the manner described. In addition, he must, before the poison is delivered, affix his signature to an entry made by the seller in the Poison Register.

If a purchaser requires a substance in the first schedule for the purpose of his trade, business or profession only, he may be supplied subject to the following conditions:

(1) The seller must receive before the sale an order in writing giving the name and address and trade, business or profession of the purchaser; the name and quantity of the article and the purpose for which it is required.

(2) The order must be signed by the purchaser, and the seller must be reasonably satisfied that the signature is his and that he carries on the trade, business or profession stated, which is one in which the poison is used.

(3) If the article is sent by post, it must be registered.

(4) The order must be kept by the supplier and numbered, the particulars must be entered in the Poisons Register and in the last column, the words "signed order" must be written, together with the number of the order.

Labelling. The provisions of the Act and rules relating to the labelling of poisons apply with limited exceptions to all transactions involving substances containing poisons.

The label of a poison or of a substance containing a poison must bear the following particulars:

(1) The name of the poison: if the poison is named in the Poisons List, the name in the list must be given. If the poison is described in the list by a group name and is not itself named, the name used must be the name or synonym or abbreviated name used to describe the poison in *The British Pharmacopoeia* or in the *British Pharmaceutical Codex*, or in any supplement to either, followed by B.P. or B.P.C. If the poison is described in neither of these books, the accepted scientific name or name descriptive of the true nature and origin of the poison must be used. If the poison is contained in a preparation in the *Pharmacopoeia* or in the formulary of the *Codex*, the name, synonym or abbreviated name of the preparation followed by the letters B.P. or B.P.C. may be given instead of the name of the poison.

(2) The proportion of the poison to the other ingredients: if the substance containing the poison is a preparation of the *Pharmacopoeia* or of the *Codex*, the proportion of the poison need not be stated if the preparation is named by reference to its *Pharmacopoeia* or *Codex* name. The proportion of the poison present in other substances may be stated in any convenient manner. If it is stated as a percentage, there must be an indication whether the percentage is calculated on a basis of weight-in-weight (w/w), weight-in-volume (w/v), volume-in-volume (v/v), or volume-in-weight (v/w). Where a substance contains among its ingredients a preparation of the *Pharmacopoeia* or of the *Codex* which contains a poison, it is not necessary to state on the label the proportion of the poison to the other ingredients if the proportion of the preparation is declared.

(3) The word "poison" or the prescribed indication of character: poisons and substances containing poisons must be labelled with the word "poison" or with the other prescribed indication of character. It is permissible to label substances not in the Poisons List with the word "poison" but it is undesirable that such a practice be freely adopted.

Substances included in the first schedule must be labelled with the word "poison" or other prescribed indication of character either in red letters or set against a red background. The words must be either on a separate label or surrounded by a line. Within this line there must be no other words except those words (name of poison, proportion of poison, and name and address of seller, or the words "Not to be taken" or "For external use only") with which the container of the poison is required by the rules to be labelled.

(4) The name of the seller and the address of the premises: the container of a poison must be labelled with the name of the seller and the address of the premises on which it was sold. To this general rule there are two exceptions in favour of wholesale distributors.

Firstly, when an article is sold by a wholesaler for the purpose of being sold again in the same container (i.e., when it is sold to a retailer) it is not necessary for the wholesaler's name and address to appear on the label.

Secondly, when a poison is supplied from a warehouse or depot it is not necessary to state the address of the warehouse or depot. The container may be labelled with the address of the supplier's principal place of business, or with the address of the registered office of a company if the supplier is incorporated. When such a poison is subsequently retailed to the public it must be labelled with the address of the premises on which it was sold.

The Isle of Man and the Channel Islands are included in Great Britain and poisons supplied to these places are, therefore, not exported. They are labelled in accordance with the Poisons and Pharmacy Act of Great Britain.

Containers. All containers of poisons must be impervious to the poison and be sufficiently stout to prevent breakage from handling and transport. Glass bottles containing liquids which are not human medicines to be taken internally must be fluted vertically with ridges or grooves recognizable by touch. This does not apply to bottles of a greater capacity than 120 fluid ounces. There is no rule as to the colour of bottles.

Poisons in the U.S.A. There are no existing regulations governing the sale or storage of poisons used in photography, and they can be obtained from chemists without the need for any permit. R.L.T. & J.Br.

POITEVIN, ALPHONSE LOUIS, 1819–82. French engineer, chemist and photographic inventor. Made numerous investigations on galvanography (1847), engraving of daguerreotypes, photography with iron salts, photolithography, photo-ceramics, the reaction of chromates with organic substances (e.g., glue). In 1855 he laid the foundations of both collotype and pigment printing (carbon printing) and also produced direct photolithographs in halftone on grained stone coated with bichromated albumen.

Biography by R. Colson (Paris 1898).

POLACOLOR. Proprietary diffusion-transfer system of colour photography, yielding a positive dye image on development in the camera within about one minute of exposure.

See also: *Diffusion transfer.*

POLAND. There have been photographic enthusiasts in Poland since the introduction of the daguerreotype, and today photography has a wide and active following throughout the nation.

History. Jedrzej Radwanski, a Polish physicist and chemist, is said to have been the first

amateur in Poland to take a daguerreotype photograph (1839). The first professional was Moritz Scholz (1842), a German, connected with Volmer's plated-ware factory in Warsaw. It is interesting to note that J. Fraget, another plated-ware manufacturer, also took orders for daguerreotypes in 1839.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In 1845, Karol Beyer opened the first professional photographic studio. His work included daguerreotype photography, photography on china, archaeological photography, numismatic and ethnographic photography, lithography, and later photolithography.

The inventors of certain photographic techniques at this period were Poles, though their nationality is not generally known as having been Polish. O. Anschütz, for instance, a pioneer in the photography of movement, was a Pole from Leszno (originally Anszyc). Warnerke, a pioneer in the use of materials sensitive to light, was also a Pole, originally called Wladyslaw Malachowski.

Many technical improvements were made by Polish photographers in the last decades of the nineteenth century and the first of the twentieth. Proszynski anticipated some of the achievements of the Lumière brothers in cinematography. He also produced the first mechanically operated film camera and a three-blade shutter for film projectors which cut out flicker.

Szczepanik was another inventor who worked on colour photography, using three filters and simultaneous three-fold projection. He used a film embossed with lenticular ridges in colour photography (a system later adopted in the Kodacolor method).

Industry. The Polish photographic industry began to develop at the end of the last century. In 1888 Piotr Lebiedzinski opened a photographic paper factory in Warsaw; he produced the Bromogravíura paper which gave pictures with a glossy surface in the light places and matt in the dark. He devised various applications of photography to industry, including a photographic method of checking distortions in railway tracks which was widely used in some countries for many years.

After the first World War a number of factories in Poland began producing photographic equipment: the Foton factory, Ero, Stafra, etc., and one in Bydgoszcz which is still working today. The Fos factory in Warsaw at that time produced very good quality lenses.

It is worth noting that Marie Curie-Sklodowska published one of her first articles on her discovery of polon in the photographic monthly *Swiatlo* (Light) in 1898.

Artistic Aspects. The beginnings of photography as an art can be traced in Poland to the year 1891, when a group of enthusiasts founded the Klub Milośników Fotograficznych (Club of Photographic Amateurs). A year later the Towarzystwo Fotografików Milośników (Society of Amateur Photographers) was founded in Cracow. These organizations at first embraced only people of means, who treated photography purely as a hobby and never realized its wider potentialities.

The first Polish journal devoted to the problems of photography appeared in 1898 and was called *Swiatlo* (Light). It was followed by *Fotograf Warszawski* edited by Karolyi, *Kalendarz Warszawski* edited by Uminski, and by *Miesiecznik Fotograficzny* edited by Huber, Mikolasch and Switkowski.

At this time there were a number of genuine enthusiasts who believed that amateur photography offered the true basis for the creation of a photographic art. Even so, after World War I, when cameras became cheap enough to be owned by the man in the street, most people were mere snapshooters and all attempts to raise photography to a higher artistic level by publications or club activities failed for lack of support.

Only a few amateur clubs treated photography as an art. These clubs were of two types. There was the Stowarzyszenie Foto-Amaturów (Photographers' Association), which accepted any amateur, and the Foto-Klub (Photo Club), which accepted as members only photographers with artistic achievements to their credit.

Jan Bulhak has been the greatest personality in the history of Polish pictorial photography so far. He was the founder of the pre-war Polish Photo-Club, for amateurs specializing in pictorial photography. In the post-war Poland he was one of the founders and the first president of the Zwiazek Polskich Artystów Fotografików (Union of Polish Photographic Artists). His death in 1950 was a great blow to Polish photographic art.

Polish pictorial photography of the interwar period was characterized by a formalistic search after pure lens effects, theatrical compositions, blind addiction to specialized techniques, and a general tendency to make photographs resemble paintings in form and texture.

But a few artists refused to submit to the generally accepted standards of the period and sought to depict the beauty of the homeland. Others developed the artistic portrait, a portrait with psychological meaning.

The war destroyed practically all the achievements of Polish photography but as soon as the war was over the social and political emancipation of the Polish people brought about the emancipation of photography. It now became established as one of the arts.

The whole photographic life in the country has since the war been rebuilt on a completely different basis from that existing before September, 1939.

Organisation. *Zwiazek Polskich Artystow Fotografikow* (The Union of Polish Photographic Artists) was established in 1946. It is a small organization with 290 members, and the conditions of acceptance are exacting. Candidates, before their applications can be considered, must prove a minimum of three

years' artistic experience, participation in exhibitions at home and abroad, and publication of a selection of works of their own. Graduates of the Cameramen Section of the Higher School of Films, and photo-reporters who are members of the Union of Polish Journalists can also apply.

All candidates for membership of the Z.P.A.F. must also present, with their application, 20 examples of their own work for approval by the Union's Artistic Commission.

The Z.P.A.F. acts as the representative of Polish photographic art at home and abroad (via F.I.A.P.), organizing exhibitions at home and selecting exhibits by Polish photographers for international exhibitions.

The Z.P.A.F. organizes annually an All-Polish Exhibition of Artistic Photography, which is a survey of the Z.P.A.F. members' achievements, and eight regional exhibitions in provincial centres by the branches of the Union. Each year mobile exhibitions visit cities with particularly lively cultural activities and there are approximately 10 individual exhibitions.

Within the framework of cultural interchange with other countries, the Z.P.A.F. organizes annually several exhibitions abroad and, in return, exhibitions by foreign photographers in Poland. Every three years the Z.P.A.F. organizes an International Exhibition of Artistic Photography in Poland. Such events are very popular, and the All-Polish Photography Exhibition in Warsaw is, on the average, seen by some 40,000 visitors.

The Z.P.A.F. published a Yearly Almanac of Polish Photography with approximately 150 examples of the most outstanding works by Polish photographers.

Together with delegates from all the other creative unions, the Z.P.A.F. is represented on the Cultural Council, which is an advisory body to the Minister of Culture and Art. Members of the Z.P.A.F. also serve as artistic consultants to publishing houses and other institutions which concern themselves with artistic and technical photography.

The Z.P.A.F. receives a subsidy from the state which, apart from meeting administrative costs, supplies large sums for the Union's publishing activities, enabling the Union to house its exhibitions in the best available premises. The state in addition grants 10 creative scholarships annually and also finances trips abroad for 2 or 3 of the most outstanding Polish photographers. Another example of patronage by the state is the purchase of work from All-Polish and Individual Exhibitions, which will be included one day in the proposed Museum of Photographic Art. City Councils provide annual awards for the most outstanding artists, including photographers. In all cultural negotiations with other countries, the Z.P.A.F. is the State's representative of Polish photographic art, and the organizer of artistic exhibitions.

CC-0. Kashmir Research Institute, Srinagar. Digitized by eGangotri

Amateur photographic activities, like the amateur activities in other artistic spheres such as painting, sculpture, music, etc., are organized by Cultural Centres, industrial enterprises and institutions, and by schools. All these amateur photography units together constitute the Federation of Photographic Societies whose aim is to popularize photography as widely as possible. At the more advanced amateur centres members of the Z.P.A.F. act as instructors and advisers. A.Jo.

POLAR CURVE. Graphic method of recording the distribution and intensity of light emitted from a source. Points of equal light intensity are plotted along lines radiating from the source over the angle including the emitted rays. When these points are joined up, the result is a polar curve.

Thus, polar curves of a lamp in different types of reflector show at a glance the way in which the light is distributed over the scene in front and indicate the distances from the lamp in all directions where the light intensity—and hence the required exposure—are the same.

Illuminating engineers use polar curves of lamps and fittings when they have to ensure a minimum level of illumination over a given area—e.g., in a schoolroom or a factory machine shop.

POLAR CURVE. This shows in the form of a graph the light distribution at different angles to the axis of the lamp unit. A bare lamp emits the light evenly all round; its polar curve would thus be a complete circle centred around the pole. Here the solid curve represents the highly directional light of a grid filament spotlight, the dotted curve a ring filament spot.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

POLARIZED LIGHT. Ordinary light can be regarded as travelling in waves that vibrate in all directions at right angles to the direction along which the light is travelling. Certain crystals will only allow electro-magnetic waves to pass through them if they are vibrating in one particular plane. So any light that passes through the crystal emerges vibrating in the one plane along which the crystal is transparent. Light which thus has its vibration restricted to a single plane is said to be plane polarized.

It is also a fact that most surfaces, in reflecting light, will polarize it to some extent. Glass for instance, will partially polarize light; in fact, it will effectively polarize all light rays at about 56° to the normal to the surface.

Some organic materials, treated by stretching and orienting the molecular structure, will also polarize light. These materials can be made into films for use in filters over camera lenses.

Filters. Polarizing filters will reduce the brightness of reflections from polished or glossy surfaces providing the angle of reflection is between, say, 70° and 40° to the normal. Much has been written about the usefulness of polarizing filters but it must be said in all fairness that natural conditions very often render such a filter of little value. Under suitable circumstances however, polarizing filters are useful when photographing shop windows through the glass front, copying pictures behind glass, photography of polished furniture (where the reflected glass tends to hide the grain of the wood) and similar purposes.

POLARIZING FILTER. The polarizing filter absorbs all light which does not vibrate in its own plane of polarization. As the filter is rotated across a beam of polarized light, the intensity of the beam is progressively reduced as the component vibration in the plane of the filter gets less. With its plane of polarization at right angles, the filter cuts out all light.

POLARIZED LIGHT. Top left: Normally light waves vibrate in a large number of planes about the axis of the light beam. Top centre and right. If the waves vibrate in one plane only, the light is plane polarized; e.g., as after passing through a polarizing filter. Centre to bottom: The action of a polarizing filter is analogous to that of a picket fence on a vibrating rope.

Polarizing filters can be used to darken the blue sky, the light from which is to a large extent polarized when the sun is in a specific position in relation to the relevant area of sky and they are, in fact, the only filters that can be used with colour films without affecting the reproduction of other colours.

Many photographic ends and effects may be achieved by the use of polarizing filters over the lens, the light source (artificial), or both.

Photographic Applications. Polarized light is used in a variety of scientific fields to show up and photograph phenomena which would not be visible by normal light.

The technique is the same in most cases. The object to be examined or photographed is placed between two crossed polarizing filters. Normally these would stop all the light from coming through. If, however, the object affects the polarization of light—by rotating the plane of polarization, by depolarizing the light, or by turning it from plane to circularly polarized (i.e., where the plane of polarization is not flat but twisted like a spiral staircase)—it will become visible from behind the filters.

In photo-elastic stress analysis, scale models in glass or transparent plastic of structural engineering units such as girders, etc., are

subjected to stress and photographed between two crossed polarizers. Under these conditions the most stressed sections have the strongest effect on the polarization, and an exact stress distribution can be seen in the picture. Owing to interference the stress patterns also show light and dark fringes, the direction of which indicates the direction of the maximum stresses.

In photomicrography polarized light helps to identify certain compounds which rotate the plane of polarization. Where crystals are photographed, the structures will show complicated colour patterns which may have a pictorial as well as a scientific value—especially if taken on colour film.

A rather different application of polarized light is the Kerr-cell shutter used in high speed photography. This relies on changes in polarizing properties of liquids in a high voltage electric field. R.B.M.

ONE-MINUTE CAMERA. Land camera, utilizing image transfer by diffusion. The lower roll holds the light-sensitive negative paper, the upper roll the non-sensitive positive paper. The image is exposed on the negative paper; after exposure the negative and positive papers pass between rollers which press them into contact and spread a film of jellied processing reagent between them. After one minute, the finished positive can be removed on opening the camera back.

POLARIZING FILTER. Special type of filter used in front of the camera lens to cut out unwanted reflections. The filter will only transmit light polarized in a particular plane so that it can be rotated to hold back any light rays that have been polarized by reflection from a polished surface—e.g., a shop window.

See also: *Polarized light.*

POLAROID LAND CAMERA. Trade name of still camera using a diffusion-transfer process to yield finished positive prints within about 10 seconds (black-and-white) or one minute (colour).

The first model of this camera, and also the first camera for general photography using a diffusion transfer system, was introduced in 1948 and produced brown positive prints in one minute. Subsequent developments led to black-and-white prints, to a reduction of the processing time to about 10 seconds, and to special materials yielding black-and-white transparencies, recoverable black-and-white negatives and colour prints. The effective speed of black-and-white materials for this system ranges up to 3,000 A.S.A. (10,000 A.S.A. for special purposes).

The camera takes a negative sensitive material (paper or film) and a non-sensitized positive paper, in two separate rolls. The positive roll also carries pods of jellified developing reagent.

THE STEPS IN THE POLAROID PROCESS. 1. In the camera exposure forms a latent image in the usual way on the negative material. 2. On pulling the tab, the processing rollers squeeze the reagent pod between the negative and positive material to start development. 3. The negative image now develops in the negative layer while the unexposed silver salts diffuse into the positive layer to form the positive picture there. 4. At the end of the processing period (usually as little as 10 seconds) the positive print can be peeled away on opening the picture door in the camera back.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

POLAROID SHEET FILM OPERATION. The sheet film, consisting of a negative, a positive and a paper cover plus the reagent pod, is loaded into a special sheet film holder which can be used in most plate cameras. 1. On inserting the film in the holder a clip engages inside and holds the negative film in place. 2. For the exposure the paper cover and the positive paper are withdrawn. 3. After the exposure the paper cover and positive are pushed back again and the processing rollers closed up. 4. On withdrawing the whole sandwich the reagent spreads between the negative and positive layers to start the processing reaction. Processing takes place outside the sheet film holder and the negative and positive are then peeled apart.

The body, shutter, focusing and other camera features follow conventional folding camera lines, but the back is designed to take the two rolls and also to provide for their processing inside the camera. The camera is loaded in daylight and the negative paper or film drawn into position to face the lens for the first exposure.

After the exposure, pulling a strip of paper projecting from the camera brings the exposed negative behind the pressure plate and draws it—in contact with the positive paper—through a pair of steel rollers. Their pressure bursts the pod containing the processing reagent and spread the latter evenly between the two surfaces. This initiaties the diffusion-transfer processing, during which the negative image is developed and the positive formed in the non-sensitized paper layer by diffusion of the unused silver salts into this layer. Processing takes place in a special compartment in the rear of the camera; after the appropriate time a door in the camera back is opened to reveal the back of the positive paper strip. This is perforated around the edges of the picture, and can be lifted out by means of a small tab, by breaking the perforations. The finished print is slightly damp, but completely developed and fixed when peeled off the negative paper.

An alternative camera design takes the negative and positive papers in the form of single cut sheets inside a holder resembling a film pack container. The negative sheets are here stacked on top of each other behind the picture aperture. After each exposure, pulling a tab draws the negative and an associated positive sheet between pressure rollers (which spread the developing reagent between the two surfaces) right out of the camera. Processing here takes place outside the camera and after the appropriate time the negative and positive sheets are peeled apart.

Sheet film adaptors for press and technical cameras take single pairs of negative and positive material. These are packed light-tight, and after exposure in the adaptor are pulled out between pressure rollers which once more spread the activating reagent between the two parts of the sandwich. After the development outside the holder, the negative and positive are stripped apart.

Polaroid roll film backs—without the optical camera elements—also exist for fitting to technical and special cameras for oscillograph recording etc. L.A.M.

POLAR PHOTOGRAPHY

Low temperatures offer special photographic problems, both in the manipulation of apparatus and in taking technique. A distinction is, however, necessary between cold weather conditions prevailing in the winter in temperate climates, and sub-zero temperatures met with in the arctic and antarctic regions.

Temperate winter conditions involve temperatures around or a little below the freezing point of water—ordinary cold weather photography.

Polar photography implies temperatures down to − 40° to − 70° F. (− 40° to − 55°C.). These appreciably affect equipment and materials as well as the comfort and work of the photographer.

The problems relating to equipment include greatly increased viscosity of normal lubricants, leading to sluggishness in the moving parts of the camera; brittleness of shutter blinds and film supports; freezing of condensation on cameras and lenses, etc.

CC-0. Arunachalam Digital Preservation Foundation Chennai

The effect of cold on the photographer influences the way of holding and handling the camera, visual observation (including the use of snow glasses), etc.

EQUIPMENT

There is no special photographic equipment manufactured exclusively for polar use, since most apparatus will serve satisfactorily with a certain amount of adaptation.

Camera Types and Features. The choice of camera is governed by operational features as well as purpose. For arctic or antarctic expeditions, saving weight is often important so a miniature camera has obvious advantages on journeys in the snow and away from the base of an expedition; and its extra lenses, filters, etc., do not greatly add to the total weight. Also the 36-exposure load of 35 mm. film cuts down on the reloading required.

Many people like to use precision twin lens reflex models. Advantages are the absence of bellows, large focusing knobs, viewing without putting the face or eye close to the camera, automatic shutter tensioning, and easy film transport. All the manipulations of picture taking can be carried out with mittens on the hands. However, it is important to avoid breathing on the focusing screen.

Folding roll film cameras are also in use, but the controls are more difficult to set with mittens or gloves.

On polar expeditions it is useful to have at least one medium-size plate camera at the base of the expedition. This serves for high-quality colour shots intended for reproduction, as well as for more advanced survey and similar work.

Bellows cameras should be fitted with first-quality leather bellows not loaded with too much stiffener. Plastic bellows are liable to crack in polar climates. Rigid cameras with extending lens tubes are free from such risks.

Eye-level viewfinders present a risk: a cheek brought in contact with them at temperatures below − 15° F. (− 26° C.) may suffer instant frostbite. If the skin is wet, it will also freeze to the metal. For constant use the eyepiece should be surrounded by fur or cloth. Even rubber eyepieces (as fitted on some cine cameras) can cause freezing of the skin. Frozen rubber becomes brittle, liable to fracture, and spare eyepieces should form part of the kit.

Whatever the equipment of an expedition, it is always advisable to include a simple box-type camera ready for use by anybody at any time.

Cine Cameras. Motors on cine cameras may become unreliable at very low temperatures, and drop in speed even if winterized (see below). Electrically driven equipment suffers from the effects of cold on the batteries. Below 0°F. (about − 18° C.) the current output drops, and at − 10° F. (− 23° C.) becomes insufficient to maintain proper operating speeds for a run of 10 feet.

Accumulators, particularly of the nickel type, are somewhat better and can be used down to − 35° F. (− 37° C.), but are heavy. A silver accumulator weights only 1½ pounds for a 9 volt pack, and will drive a large 16 mm. camera for 7,000 feet at one charging. Because of its small size (2 × 4 × 6 ins.) it can also be carried under the clothing, so that body heat helps to maintain it at operating level.

Winterization. Since most lubricants used in photographic equipment become almost solid in polar climates, special winterization is essential for all apparatus. This consists of degreasing the moving parts, including the shutter, and lubrication with either graphite or a silicone lubricant. The job is best undertaken by an expert, preferably the manufacturer.

Winterization should extend to film transport mechanism, opening and closing movements of the camera, and also to focusing lens mounts. A lens which functions smoothly at normal temperatures may require a pipe wrench to turn it at − 50° F. (or about − 45° C.). This applies particularly to cine lenses because their small diameter and narrow focusing rings make them very difficult to grasp with gloves. A useful device to overcome this difficulty is to thread a small bar radially into the control ring, in much the same manner as is done for zoom lenses, for easy rapid use.

Shutters. Unwinterized shutters cease to be accurate even at moderately low temperatures of 20° F. (− 6 or 7° C.). With suitable low-temperature lubrication diaphragm shutters will work well under all conditions.

Focal plane shutters other than all-metal types are more difficult to lubricate for extremes of temperature, and also suffer from other disadvantages. Thus the opaque material of the blinds easily cracks, and may flake off.

Tensioning of shutters—of any type—should be done slowly to avoid breaking springs. This also applies to other spring-loaded camera parts.

Lenses. Apart from stiffness with normal lubricants in the focusing movement, and condensation, uneven expansion on rapid warming up may cause trouble. With a lens in a heavy focusing mount this may lead to cracking of components. It is more likely to happen with highly complicated lens systems with strongly curved elements. The uneven response of different types of optical glass to temperature changes may separate cemented units.

In all cases the camera should therefore be warmed up very gradually when it is brought indoors from sub-zero temperatures. Certain authorities consider it best to leave the equipment out of doors at all times. If this is done, it will be wise to tension and release the shutter several times before use. Similarly, a short run in a cine camera will help to condition it for the cold. It should, however, be noted that some experts oppose this advice, and maintain that the equipment should be exposed to low temperatures only as long as necessary.

Condensation. Condensation is one of the worst nuisances of polar photography but fortunately does not last very long. Cold instruments brought into warm or moist rooms will promptly collect a sheet of ice. Care should be taken never to blow or breathe on a lens when cold, either inside or out of doors. Hands, if perspiring in heavy wool or fur mittens, should be bared and waved in the air for a few seconds to avoid moisture collection, especially when loading the camera. Otherwise there is a danger not only of the lens icing up, but of the fingers freezing to the metal parts of the camera.

Generally, condensation will evaporate in half-an-hour or so from the front lens element. Condensation or icing on inside surfaces may call for complete dismantling and drying out at room temperature.

Condensation is particularly bad for diaphragm shutters, as the moisture rusts and pits the blades, making smooth working impossible. The iris diaphragm is liable to suffer in the same way. Focal plane shutters are less sensitive in this particular respect.

Dropping a cold camera in the snow at low temperatures is of little consequence. Usually a brief shaking will dislodge any snow particles. With a warm camera matters are worse: thawed snow flakes will immediately form ice which will take days to evaporate (unless of course the camera is warmed and dried).

Accessories. Normally accessories carried in the field tend to be limited to tripods, filters, lens hoods, and exposure meters.

Among tripods the wooden type is less subject to damage by cold or in ice and snow than most metal tripods, and it is easier to handle as there is less risk of condensation and freezing up. Pan and tilt heads will need special attention for degreasing, etc.

A useful aid in snow is to cut a triangle of stout canvas of roughly the same size as the distance the tripod legs are spread apart. The edges are bound for strength, and a brass eyelet fixed in each corner. This should be large enough to pass the spike points of the tripod, but not the tripod legs themselves. In use the triangle may be spread on even soft snow, the tripod points inserted in the eyelets and the camera mounted for operation. This prevents the legs from sinking in the snow.

Filters for polar work should be of solid glass dyed in the mass rather than cemented gelatin (this is unavoidable with polarizing filters).

Lens hoods require no special precaution, but should be easily attachable to the lens to reduce manipulation in the cold.

Exposure meters of the best quality do not vary in reliability at low temperatures, especially if the whole unit is hermetically sealed. It is, however, advisable to take several meters on a polar expedition, as they appear to get out of adjustment more quickly.

Personal Equipment. Apart from the standard warm clothing for sub-zero temperatures, two points require special mention in polar work.

Firstly, it is advisable to wear light finely knitted wool gloves inside the heavy mittens. The thin gloves permit manipulation of camera controls, etc., for a short time when the hands are removed from the heavy outer covering. Some people prefer thin silk or cotton gloves, but once the hands are exposed to the cold—perhaps to the point of numbness—they do not warm again as readily in silk or cotton.

Secondly, snow glasses are usually essential to guard against snow blindness which, while temporary, is always irritating and very uncomfortable. The glasses may be raised for short periods for focusing or other adjustment. Spectacle wearers should have coloured spectacles prepared to their individual prescription.

TECHNIQUE AND SUBJECTS

Polar photographic technique differs from normal procedure in manipulation of the camera, and in exposure, filters, etc.

Carrying and Holding the Camera. The mere handling of intensely cold equipment is a problem, especially with all-metal cameras. Even with wool-lined leather or fur mittens great amounts of body warmth are drawn off by the chilly metal. It is therefore desirable to have sturdy leather cases for equipment if the design permits it. Large cine cameras present even more of a problem in heat dissipation, since they must be grasped firmly if hand-held.

If the camera is small enough, it is best carried under the clothing to keep it reasonably warm and thus in good working order. The photographer should not be perspiring, however, as condensation may form unless the camera is completely encased. With larger equipment the chilling effect of a cold lump of metal may be serious if tucked under a parka or inside a shirt. The use of thin polythene bags for items of equipment is a useful way of reducing the risk of condensation when they are carried in this manner.

Loading and Handling Films. The main effect of intense cold on films is to make them brittle and liable to snap, especially if curved sharply. For roll films, size 120 cameras are therefore better than those taking 620 films because the film leaves, and is rewound on to, a larger core. When curving films to attach them to spools, etc., the film base should be bent only slowly, preferably with bare hands as the body heat will aid in making the film base more pliable. Caution is important with film edges; when cold and hard they are razor-like, and can cause nasty cuts.

To avoid breakage of the film, it should always be advanced slowly in the camera.

Sheet film (in a suitable camera) can be kept flat, but involves the use of comparatively weighty holders. Film packs are unreliable in extremely cold weather, partly because the film easily splits when making the tight turn

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation Chennai

inside the pack, and partly because it is subject to static marks due to rubbing. The drier and colder the weather, the more likely such marks.

Cine film suffers from similar troubles, especially as it has to be curved and uncurved a lot and moves all the time in the camera. Magazine type cameras generally cannot start at temperatures below −40° F. or C., owing to the set that the film takes in the magazine. Most 8 mm. magazine cameras engaging only one perforation hole during film transport will tear out the film if its stiffness exerts more than 10 ounces of pull.

Exposure. An exposure meter is almost indispensable for light measurement, and the exposure is determined in the usual way.

One complication is the effect of the reciprocity failure and speed loss at very low temperatures. The effective film speed appears to drop to a minimum around − 80 to − 100° F. (− 70° C.), and rises again to its full value around − 180° F. (− 120° C.). This rise is of academic interest, since the lowest temperature at which photographs have been taken in polar regions seems to be about − 70 to − 80° F. (− 60° C.).

Black-and-white films have been found to need one stop more exposure at − 20° F. (− 30° C.), two stops more at − 40° F. or C., and three stops more at − 70° F. (− 56° C.). In practice the latitude of the film takes care of this speed loss down to − 40° F. or C. No actual figures are available for colour film, but the effect is expected to be similar. At the same time the colour balance tends to shift towards cyan. Trial exposures with compensating filters are therefore advisable. Various makes of colour film may behave differently in this respect, and the appropriate manufacturers should be consulted.

Filters. For black-and-white work with clear or partly clouded skies a medium yellow filter enhances pictorial quality. Heavier filtering is useful for special effects. An ultra-violet filter should always be used—for black-and-white as well as colour film—to cut out the high proportion of ultra-violet rays in the daylight.

Polarizing filters are particularly effective in the polar regions and surpass optical absorption filters for clear rendering of distant views. They do, however, seem to call for higher filter factors in very northern or southern latitudes—some 4 to 8 times.

The polarizing filter darkens the north sky most in the arctic, and the southern sky in the antarctic. Clouds, snow-clad mountains, and distant scenery will then stand out sharply against a blue-black background. With the camera pointing east or west, the effect of the polarizing screen is weaker; the sky tone will, however, be uneven, being much darker towards the north (in the arctic) or the south (in the antarctic). The filter factor for eastward or westward views is also somewhat less.

With high speed black-and-white film two partially crossed polarizing screens can be used as a neutral density filter over the camera lens. This helps if the snow scene is so bright that even the smallest lens aperture would still lead to over-exposure (especially in cine work where the shutter speed is often fixed). The method is less satisfactory for colour film.

Processing. Although most photographs are taken in the field, often in very low temperatures, processing is carried out at the base of an expedition or on other semi-permanent premises, and does not differ from ordinary cold weather procedure in more temperate climates. Suitable heating keeps the darkroom and solutions at workable temperatures.

On expeditions the working facilities are somewhat limited, and care is needed to keep irreplaceable equipment in working order.

Water for photography is preferably obtained from glazier ice or snow; pack-ice and icebergs contain salt, but can still be used as a source, if allowance is made during processing for the slight retardation their salt content may cause.

Applications. The rôle of photography on polar expeditions is to study geographical, geological and topographical features of the region under investigation, to record animal and any plant life, and to conduct scientific research. Photography of fossils has also established the existence of a temperate climate in earlier geological eras. Military polar expeditions have, with the aid of photography, investigated the behaviour of clothes and equipment under cold weather conditions.

Aurora Borealis, and other Effects. These sky illuminations of nature can be very impressive and picturesque, but are weak from the point of view of actinic brilliance. The brightest of them still require exposures of the order of ½ minute at *f* 2; the average, especially on colour film, is nearer to 20 minutes.

Because of the quality of the light emitted by the aurora, some lenses appear to be able to produce better images than others.

The phenomenon known as "mother-of-pearl sky" occurs occasionally every few years in the arctic and sub-arctic areas. It can be recorded by normal photographic procedure; slight under-exposure has given the most beautiful results on colour film.

Impressive arctic phenomena are the "sun-dogs". These appear as brilliant balls of fire and are caused by the reflection of the sun from ice crystals floating in the air. They are seen one above and to each side of the sun.

These phenomena are best photographed with a single-lens reflex camera or a plate model with ground glass screen, since exact positioning of the camera relative to the sun is important. The sun must be centred squarely in the lens to eliminate as much flare as possible, as well as the ghost images and reflections of the iris diaphragm and shutter blades. Care is necessary with focal plane shutters, or the sun may burn a hole in the shutter blind.

Polar Night and Day. Beyond the arctic circle the sun does not rise during the winter. That does not mean that it is darkness in a clear day there is a surprising amount of pale blue light. As the sun begins to break the horizon in spring, or descends in the autumn, the bulk of the light received from it is very red. In either case colour film needs appropriate correction filters. By late spring exposure estimation is very misleading without a meter.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The sunsets and sunrises during spring and autumn in the polar and sub-polar regions yield pictures of great beauty, especially on colour film. Again, ground glass screen focusing cameras are preferable for this type of work, as the visual appearance may not correspond with what the film records. S.M. (D.H.O.J.)

POLICE PHOTOGRAPHY. The use of photography in police work dates from autumn 1852, when the Swiss Federal Government authorized the Department of Justice and Police to have photographs taken of all vagrant beggars found in cantons other than their own. In December 1854 the governor of Bristol Gaol, England, issued a circular recommending other prison governors to follow his practice of having a photograph taken of every prisoner in his charge. The same year, a "wanted persons" notice with photograph, made according to the suggestion of Moreau Christophe, was bill-posted publicly in France. This was first done in England in 1861. It was not until 1870 that the photographing of every prisoner in England and Wales was made compulsory. The procedure was justified during the year 1871–72 when 375 arrests were made in consequence of the criminals having been identified by photographs. Today the more advanced photographic techniques are in constant and daily use by all the larger police forces of the world. Well equipped photographic departments are an integral part of police administration and their contribution, especially in crime detection, is an important one.

Great reliance is placed upon photographic evidence by the Courts of this land and hardly a major crime of any importance is solved without photographic evidence of some kind. Evidence of this type is factual, objective and without bias. For recording the scenes of serious crimes its value is inestimable.

Location Work. The photographing of scenes of crime follows well defined practice. The locus is recorded exactly as found and before anything is touched or disturbed. Nothing is moved before complete photographic coverage has been made from several angles to meet all eventualities. If bodies, articles, etc., have been moved they are never replaced in an attempt to approximate their original position. This amounts to reconstruction and reconstructed photographs of scenes of crime are not admissible as evidence in English Courts of Law. Any clues present, such as shoe prints, finger prints, bullet marks, scratches, signs of entry and egress, etc., are recorded with due regard to their relation to each other. Articles bearing on the crime, such as weapons or tools, are photographed in their exact position before removal for examination and further photography.

Wounds on bodies are always photographed as it is possible from a study of the photograph to deduce with a high degree of accuracy the shape and size of the weapon used. Tattoo marks and prominent scars are also photographed in every instance where identification is in doubt.

In recording these scenes of crime the aim is to produce a series of photographs which will tell the story of the crime. All prints must carry a good range of tones and be absolutely sharp from back to front.

Equipment for this type of work can be any good stand camera from quarter to half plate size. It should have a full range of camera movements and be fitted with a double extension. Wide angle lenses are extremely useful on occasions if used with due regard to the risk of distortion. The resultant enlargements up to 10 × 12 ins., a convenient size for presentation in Court, should be indistinguishable from contact prints.

Lighting for interior scenes of crime will vary, but the majority of cases can be covered with expendable flash bulbs. "Painting" the scene with portable half watt lighting is sometimes useful. Electronic flash, owing to the comparative low light output from the portable types, is hardly suitable where large areas have to be covered sharply and well lighted from front to back.

Comparison Records. With many offences a photograph is the only way in which the evidence can be presented to the Courts to supplement the opinion and explanation of the expert. In cases of fingerprint evidence, for instance, the similarity of the prints is quite easily followed by means of the photograph. Ballistic evidence, sometimes of a highly technical nature, is made quite clear through photography and in forgery cases the expert's evidence on handwriting is always supported by means of the photograph.

Comparison photographs, which involve photography of the "trace" found at the scene of a crime, with a known standard are frequently used by the police. Boot and shoe impressions found at scenes of crime can readily be compared with the suspect's footwear, marks made by jemmies and tools can be photographed

same-size and the instrument "offered up" to the photograph.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Identity Pictures. Photographs of the criminal aid the investigating officer in his hunt for the criminal. A true likeness is required as opposed to a portrait. Pin sharpness is essential, and under no circumstances must there be any retouching. All facial blemishes, marks and scars must be clearly delineated. Profile and full face photographs are made to ⅛th scale and full length to 1/27th scale. Special apparatus is available where large numbers have to be dealt with, but police photographers usually make use of a special back fitted on to a half plate camera which will accommodate the regulation photograph. Operating indoors under controlled lighting conditions and using time and temperature technique for processing ensures a uniform standard of print.

Questioned Documents. Document reproduction is carried out on a large scale in cases of fraud and processes such as photostat, dyeline reflex printing and Autopos are commonly used.

The examination and photography of questioned documents form a large part of police photographic work and the special properties of the invisible light rays at both ends of the visible spectrum are utilized.

Ultra-violet rays are turned to good account in a number of ways in police investigation. They are used in all cases in the preliminary examination of documents where forgery is suspected. The eradication of original written matter if effected by chemical agency and its substitution by other writing, can generally be detected; any application of chemicals to paper can nearly always be revealed because the area so treated gives off a totally different fluorescence from the remaining part of the document. Usually the original writing is disclosed and when photographed provides irrefutable evidence of forgery.

Special Applications. "Secret" writing with so-called invisible inks or urine, milk, onion juice, etc., all give a characteristic fluorescence and are generally detectable with ultra-violet light. Oil and grease stains give off a particularly brilliant fluorescence and are easily recorded. Blood stains on garments which have been washed to remove the stain can be photographed in U.V. light. Invisible laundry marks which fluoresce strongly under U.V. light are sometimes found on articles of clothing left at scenes of crime and afford valuable evidence when photographed and produced in Court.

The powers of penetration of infra-red rays are used in a variety of ways in police photography. Where written matter is obscured by other writing, scribble, dirt, oil, etc., infra-red photography will give a good recording within certain limits. Partially burnt and charred documents can be photographed with a fair degree of success. Faint pencil writing due to age, wear, or dirt can be "boosted" and rendered legible. Old scars and scarcely visible tattoo marks on bodies can be revealed by infra-red photography. These rays can also be used to determine the distance at which a firearm is discharged from the victim. Powder staining, invisible on dark garments, can be seen quite plainly on the photograph. This evidence is often of great value.

Cine photography is used in police work mainly in recording traffic and crowd control. It has been used on a few occasions to catch the criminal in *flagrante delicto*, but these opportunities, as can be well imagined, are rare. Instructional films for the training of police are made but film strips are to be preferred for this purpose, and are used extensively.

Colour photography, with its well known limitations as regards fidelity in the print, has yet to prove its worth. Colour transparencies, however, are being used on an ever increasing scale and have provided evidence on many occasions. P.G.L.

PONTI, CARLO, Dates unknown. Italian architectural photographer in the 1860s specializing in views of Venice, Padua and Verona. Made a pictorial record of Venetian street types in the early sixties.

PONTING, HERBERT G., 1871–1935. English landscape photographer and explorer. Official photographer to Captain Scott's second and last South Pole expedition 1910–1912. Author of *The Great White South* and *In Lotus-Land Japan.*

PONTON, MUNGO, 1801–80. Scottish photographic inventor, secretary to the National Bank of Scotland. Discovered 1839, while experimenting on making Photogenic Drawings with silver chromates, that paper impregnated with potassium bichromate is sensitive to light. This is of fundamental importance for most photomechanical reproduction processes. Ponton used this photographic paper to record thermometer readings, 1845.

PORRO, IGNAZIO, 1801–75. Italian scientist. Described the first tele objective in 1851 (later re-invented and manufactured by Dallmeyer, Duboscq, Miethe, Steinheil) and worked on photogeodetics in 1855.

PORTA, GIOVANNI BATTISTA DELLA. 1538–1615. Italian scientist, usually known as Gianbattista Porta. The invention of the room-type camera obscura without lens is often abscribed to him because he was the first to publish a long and clear description of it in 1558.

CC-0. Agamnigandy Digital Preservation Foundation, Chennai

PORTRAIT ATTACHMENT. Positive supplementary lens which enables the user of a fixed focus camera to take close-up pictures. Generally, the close-up picture is a portrait (hence the name), but with suitable lenses large-scale pictures of objects as small as coins, postage stamps or flowers can be brought into the scope of the sort of camera that must otherwise work at least seven feet away from its subject.

When a supplementary lens with a focal length of F inches is added to the lens of a fixed focus camera (or any camera with its lens set at infinity) the combined lens is then focused sharply on objects F inches away, and the effective aperture of the lens (and thus the exposure required) remains unchanged.

This is the principle of the portrait attachment. The photographer merely has to fit the attachment over his lens, note the focal length (usually engraved on the edge of the supplementary lens mount) and set up his camera at that distance from the subject.

SUPPLEMENTARY LENSES
WITH FIXED FOCUS CAMERAS

Supplementary Lens			*Range Covered*			
Focal Length		*Power*	*ft. and ins.*		*cm.*	
ins.	*cms.*	*(Diopters)*	*from*	*to*	*from*	*to*
—	—	—	∞	10–0	∞	300
120	300	0·33	10–0	7–6	420	225
80	200	0·5	8–0	5–6	240	165
60	150	0·67	6–0	4–3	180	125
40	100	1·0	3–9	3–0	112	90
32	80	1·25	2–11	2–5	88	73
26	67	1·5	2–5	2–0	73	60

This table assumes that the lens aperture is about *f* 11 to *f* 14.

It is possible to select a series of portrait attachments in such a way that the depth of field on one lens starts more or less where that of its neighbour leaves off. In this way, using not more than about half a dozen lenses, the whole range of distances from a couple of feet to infinity can be brought into focus on a fixed focus camera.

See also: *Close-ups; Supplementary lens.*

PORTRAIT LENS. Lenses intended specially for portraiture do not have to be designed to cover wide angular fields of view. Usually, the focal lengths selected are large in relation to the size of negative in order to avoid the unpleasant distortions of perspective created when the camera viewpoint is too near the subject.

The first lens designed for portraiture was made by the Hungarian, J. Petzval, in 1840. The acceptance of a narrow field of view permitted him to utilize two widely separated doublet components which provided what was, in those days, the remarkably wide relative aperture of about *f* 3·6. This basic lens form has been modified in a variety of ways to suit different optical requirements, but nearly all the derivations are known as Petzval lenses.

The Petzval lens has the characteristic of yielding very sharp definition in the centre of the field with a very rapid deterioration of quality towards the edges. This variation between needle sharp central definition and poor edges is not always desirable or pleasing in portraiture and in more recent times there has been a demand for a more uniform type of definition at a softer or more diffuse level than that produced in the centre of the field of a Petzval lens.

Definition Control. Where the definition of a good modern lens is too hard for portraiture the necessary softness can be produced by devices such as diffusion discs in front of the camera or enlarger lens. There are several methods, both good and bad, of artificially softening definition in this way.

In normal photography every attempt is made to produce a standard of definition as near perfect as possible—i.e., to get the lens to yield a perfect point image of a point in the object. This is not usually the ideal type of image for portraiture; softer definition is obtained if the point image is surrounded by a circular fringe of light of low intensity. By retaining the point image as a hard nucleus in the image patch the lens designer can maintain the ability of the lens to record fine detail and he can vary the degree of softness by controlling the diameter of the fringe and the relative light distribution between it and the hard central nucleus.

This type of image formation can be provided by deliberately introducing a type of optical error in the lens known as spherical aberration. It cannot be provided by merely moving a well corrected lens out of focus, as this gives an image patch of finite size but with a more or less even distribution of light intensity, so that spread of light is too severe and the effect is to spoil definition instead of softening it.

There are two main types of portrait lens constructions which soften the image by introducing spherical aberration: in the first type the amount of aberration is fixed, and in the second, it can be varied.

Fixed Aberration Lenses. In the first type there is a fixed and substantial amount of spherical aberration and at full aperture the image patch corresponding to a point in the object has a pronounced fringe round the central nucleus. When the aperture of the lens is stopped down, the fringe gets smaller until, at about *f* 16, it is

negligible and the definition is hard and sharp. In this type, therefore, softness is controlled by choice of relative aperture.

Where a marked degree of softness is not required, some normal lenses not reaching a particularly high standard of performance in other branches of photography can act in a similar manner.

Variable Aberration Lenses. In these types the softness of definition is under control at any aperture. These forms are usually derived from the basic Cooke-Triplet construction with provision for moving one or more of the lens components in relation to the others. This device introduces a variable amount of spherical aberration without seriously impairing the correction of other optical errors. Softness of definition also varies from aperture to aperture, but the control of softness at each aperture is particularly useful when exposure times and illumination levels are dictated by conditions outside the photographer's control.

When using portrait lenses of the second type it is important to realize that the relative movement of the lens components also changes the focal length and the position of focus. For this reason it is essential to focus on a screen in the camera at the aperture and diffusion setting that are to be used in making the exposure.

Focal Length. The focal length of a portrait lens is generally longer than normal in relation to the field covered. Where the normal lens has a focal length approximately equal to the diagonal of the field covered—equivalent to an angular field of about 55°—the portrait lens may have a focal length equal to $1\frac{1}{4}$ times the diagonal—equivalent to an angular field of 45°.

Portrait lenses are available in focal lengths from 1 in. (25 mm.) for 16 mm. cine cameras to 18 ins. and over for use on 8 × 10 ins. studio cameras. G.H.C.

Book: *Photographic Optics*, by A. Cox (London).

PORTRAIT SERIES. In commercial studios these are produced with a semi-automatic camera (Photomaton or Polypose) which enables an unskilled operator to take a series of portraits and deliver a finished strip or sheet of prints. Machines of this type are popular in large department stores.

The sitter is posed under a standard lighting arrangement and the operator simply moves levers to focus, expose, and transport the negative material. The negative material usually consists of a single plate. Only a small section is exposed at a time, and the plate moves to bring successive sections behind the lens until the whole surface has been exposed. One popular system gives 48 exposures measuring $1\frac{1}{4} \times 1\frac{1}{4}$ ins. in 8 rows of 6 on a 9 × 12 ins. plate. The customer is given a contact print of the plate from which he makes his own selection for enlarging.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PORTRAIT STUDIO. Modern portrait studios have developed with the psychology as well as the photography of the sitter in mind. They have grown to be a very different proposition from the early studios where gaslight and daylight were combined in a sort of greenhouse, equipped with clamps to screw the victim's head in position, and prodigiously bulky cameras. In those days it was said to be more pleasant to visit the dentist than the portrait studio.

Throughout the country to-day there are innumerable studios specializing in portraiture. These mostly consist of a small studio with a reception room, and the minimum space for darkrooms. In every case, the studio is tastefully decorated and shows the minimum amount of apparatus. The less ambitious may have walls decorated in pastel shades, bright chintz curtains, and a bowl of flowers on the window-sill. More elaborate establishments may boast of decorative hangings, a period fireplace, and other "props" which give the studio the necessary atmosphere and are also useful as settings.

Equipment. Many studios retain the large studio camera mounted on its heavy table-stand, especially those studios which use contact prints from large negatives to allow for extensive retouching on the negatives. But it is becoming more usual to find a smaller camera of modern design standing unobtrusively in a corner, with lighting equipment that blends with the general scheme of the room.

Portrait studio lighting equipment usually consists of a top-unit where a row of large half-watt bulbs mounted in reflectors provide a bright general light with the minimum amount of shadow. Facial modelling or roundness is achieved with screened floodlights to the right or left of the sitter and the equipment is completed by a good focusing spot for adding local emphasis highlight.

In recent years many of the larger studios have installed high powered speed flash equipment. This allows both brief exposure times and a small lens aperture to be used, to capture fleeting expressions sharply on the film. Such equipment is particularly popular for colour work.

The lights usually also have a low powered half-watt modelling light in each reflector, making it easier to position the lights for the effects desired.

Unlike the commercial studio which has to be prepared to handle a variety of subjects, the portrait studio is concerned with one subject only, and its size as well as the possible viewpoints are limited. So most of the portrait studio equipment can be arranged in advance, leaving only minor adjustments to be made when the sitter arrives. Lights are often fixed on extendible arms, or on easily moved wheeled stands with cables from the ceiling. The atmosphere aimed at is that of a private apart-

ment rather than a technical work-room. In many cases the subject hardly knows when the actual exposure has been made.

CC-0. Arunachalam Digital Preservation Foundation, Chandigarh

Children. Child photography is a very important branch of the portrait studio. Every portraitist has a personal technique; but all seek to create a feeling of freedom and provide something to occupy the young mind. Toys are a necessary part of the studio "props". Complicated apparatus is kept well out of sight, and portable gadgets out of harm's way. The success of the photograph largely depends upon the photographer's ability to handle his subject.

With a young, highly imaginative mind there is no need for expensive and elaborate diversions; ordinary objects and simple ideas are always more successful in establishing the state of mind required.

The psychological reactions of the child must be borne in mind in designing a portrait studio. Apparently trivial points can exercise a profound effect on the mood of the sitter: doors that stick, or that look heavy and as though they would take a lot of effort to open. All such things, and any suggestion of technical mystery tend to destroy the desirable atmosphere of freedom.

Expression. The retouching department is an important part of the portrait studio. The camera, left to itself, does not always give the most attractive rendering of the human face.

Special lighting facilities help to produce more pleasing results, but even so, few people like to see their faces as they appear in an unretouched photograph. This is not vanity; we apply it to our friends as much as to ourselves. The reason is that we are accustomed to see a face in a state of animation. Constantly changing moods and expressions follow one after the other. A still picture freezes one particular expression or one viewpoint to the exclusion of all else; we see in the picture a single phase, instead of the complex sequence we are accustomed to.

Early attempts to soften the too-factual vision of the lens introduced gauze screens and a strange assortment of other objects into the studio. These have their modern equivalents in many studios. On the other hand there are studios that deliberately go in for hard lighting to emphasize character, particularly in photographs of men and elderly people. Such studios have no retouching department in the accepted sense of the word. But in the average studio the camera operator with his lights (and perhaps, a soft focus lens) and the professional retoucher work together as a team to give the public the type of portraits it prefers. And the studio is planned on the basis of this partnership.

Colour. By making use of negative colour film, in conjunction with the services of a commercial colour laboratory, even the small studio can supply colour portraits at a reasonable price. Natural colour photography has almost entirely replaced the hand coloured portraits which used to be popular.

B.A.

See also: *Portrait studio camera; Studio; Studio photography.*

Book: *The Business of Photography*, by C. Abel (London).

PORTRAIT STUDIO CAMERA. Type of camera intended for taking portraits, full-length figures, and small groups arranged at one end of the studio and illuminated principally by fixed massed lighting. It is designed to move about on wheels but can be instantly anchored in any position. All controls are large, easy to handle, and silent. The whole design and construction of the camera are aimed at distracting the attention of the sitter as little as possible.

As most studio photographs have to be retouched, the camera is made for large negative sizes—never smaller than half plate, and generally whole plate or 8 × 10 ins.

As it is used exclusively for photographing people in more or less standardized poses under the same sort of lighting conditions, the camera has no use for camera movements like swing back and rising front, and it has no need to be either collapsible or portable.

Camera Body. The body consists of a baseboard with a lens panel and plate back, both of which can be racked backwards or forwards. An extra-long bellows is fitted and the camera has a generous extension to allow the use of relatively long focus portrait lenses. All focusing controls and movements are operated by large hand-wheels or handles. The body is supported on an elaborate stand on wheels which has controls for raising, lowering, and tilting the head, and a device for locking the wheels when once the camera has been pushed into position.

Lens. The studio photographer does practically all his work with lenses of 10 ins. or more focal length and apertures seldom larger than $f4{\cdot}5$. Most of the lenses used in portrait cameras have a certain softness of definition; this softness can be achieved in several ways, including the exploitation of certain lens aberrations. In some cases the degree of softness can be controlled by stopping down.

Shutter. The favourite shutter for portraiture is the silent-opening, "eyelid" type. This type of shutter is quite noiseless and does not need to be pre-set. It is opened by pneumatic pressure applied by an indiarubber ball held in the operator's hand and connected to the shutter mechanism through a long flexible tube. The shutter stays open until the operator releases the pressure, and the whole action is so silent that the sitter may not even notice.

Negative Carrier. The back of the camera is equipped with a special negative carrier designed, like the shutter, to be smooth-working and noiseless. It consists of a grooved frame

carrying a special type of plate holder which is inserted into guides on the camera back.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The guides also carry the focusing screen so that when the plate holder is pushed into position for exposure, the focusing screen automatically slides out of the way. At the same time, a stop on the negative frame engages with the dark slide of the plate holder and uncovers the plate as it is pushed into position. After exposure the dark slide covers the plate once more as the holder is withdrawn.

PORTRAITURE

Taking portraits can be one of the most rewarding branches of amateur photography and at its highest level it is probably the most difficult work in which a professional can specialize. This is because a successful portrait demands perfect photographic technique, a very definite measure of artistic ability and a flair for handling human beings.

Individual style shows itself here more than in most kinds of photography, but there are certain basic principles that are common to every approach to the subject. These basic principles are concerned principally with the methods of controlling the subject and the lighting.

POSING THE SITTER

The successful portrait photographer is interested in people and can put them at ease, and remain at ease himself while he is taking a portrait. He uses the technical processes purely as a means to arrive at a live and characteristic likeness of the subject. He never forgets that his own mental attitude has an effect on the sitter, and he takes a keen and personal interest in the portrait in hand. His trained observation allows him to see a characteristic pose or expression, even during a session that is sometimes short.

Making a portrait should be a pleasant experience on both sides of the camera, and everything depends on the personality and "managing" ability of the photographer. By keeping up a natural conversation he can break down any reserve or lack of co-operation from the sitter. He should suggest rather than command a pose, and by an occasional word of encouragement and praise, he can aid the confidence of the subject and banish camera-consciousness. A skilled photographer recognizes at once when the sitter looks and feels easy and natural, and he directs his efforts to that end. While there are many individual methods of approach, the object is always to secure a "live", characteristic portrait.

An efficient routine allows the work to proceed smoothly, without fluster or disturbance, and has a favourable influence on the sitter. Operations are usually directed from the camera, where the pose can best be studied. This arrangement allows the sitter to take up the suggested pose without having to be pushed into it by the photographer, a procedure which many people object to. Everything is done to make the sitter feel comfortable and relaxed, but the directing is pleasant and unobtrusive with a complete absence of the professional manner of earlier days. Some subjects are easy to approach, others difficult, and experience in dealing with the various types of sitter helps the photographer to the desired result without wasting time. The most successful portrait photographers are those who have cultivated this understanding of their sitters and the result shows itself in their work.

The Pose. The required natural, easy pose is sometimes a spontaneous action on the part of the sitter, but it is the photographer who decides when it looks right or directs movements to achieve it. For a head and shoulders portrait the subject is rarely taken squarely facing the camera. The body should be turned at an angle away from the camera, and the head slightly back towards the camera, giving a three-quarter or full-face view as desired. The seated model should always lean forward slightly into the picture. In a close-up the head generally fills the frame, and with suitable subjects parts of it may even be trimmed off. A feeling of action can often be imparted by giving the head a tilt either when enlarging or trimming the print.

Three-quarter length poses usually include the whole of the figure to just below the knee when seated. A slight turn of the body is again useful, and the legs can be turned sideways to avoid the appearance of fore-shortening produced when they point directly towards the lens. A more informal look is given in a man's portrait if he crosses his legs, usually by placing the one nearest the camera on top of the other.

This type of portrait includes the arms and hands, and they, too, must be carefully posed to avoid a look of angularity or stiffness. Any suggestion of arrested action is avoided by adopting only the quieter and simpler poses—e.g., a woman with her hands resting in her lap or a man resting his arms and hands on a table. Appropriate accessories that can be held naturally in the hands give the subject something to do with them, and help in achieving an unaffected pose.

A suitable chair or stool of good but not assertive design is a necessary item; it must not be too low or the knees will tend to stick up awkwardly. When the subject is elderly or important the pose should be a simple and dignified pose, but more freedom is permissible

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

with younger people, particularly in dealing with the more sophisticated and decorative types of women. The pose of the sitter—i.e., the manner of holding the body—is a vital part of successful posing: it should be neither stiff nor slouching.

Full length portraits are confined more to the display of ceremonial attire and records of formal occasions. Here, too, great care is taken to secure a well-balanced pose. The subject must not seem to be falling backward by leaning too much on his heels or a support; it is a good rule for the weight to be thrown forward slightly on the ball of the foot. Movement of the subject can be avoided by using a short exposure, but it is always as well to have a support, such as a chair or table, near the subject to prevent the slight swaying that is difficult to control. Much of what has been said about the poses for three-quarter length portraits applies equally to full lengths. The problem of filling the larger area around a full length in order to make a pleasing picture is largely a matter of suitably lighting or furnishing the background.

Expression. To please his sitter, the professional photographer must be able to secure a pleasing or characteristic expression. This requires sensitive observation on his part, and the restraint to avoid extremes. The broad grin or the hearty laugh is out of place in sincere portraiture which is to serve as a vivid and faithful record of the sitter. The expression of the subject is the mirror of the mental state and the penetrating vision of the camera reveals at once any trace of artificiality. The photographer must start by deciding whether he is to portray the transient qualities of the snapshot, or seek to create something more permanent that can be looked at over a period of time without loss of interest. An instantaneous exposure is no guarantee that the best expression will be captured; many a portrait that possesses all the freshness and spontaneity of a snapshot is the result of a time exposure lasting several seconds—it all depends upon the photographer's ability to recognize the right moment to expose.

The features that most directly influence expression are the eyes and the mouth. Apart from any mental or emotional feelings that the eyes may express, it is most important to see that they are looking in the right direction. Turning them to one side, even slightly, can give a furtive, suspicious look, and the whole effect can be ruined if they are looking too high, or too low, or half closed because of the brightness of the light. As a general rule the eyes should look in the direction to which the head is turned. Looking straight into the lens almost inevitably leads to an expression of forcefulness which may or may not be desired. If the subject habitually wears spectacles, he should be taken with them, or he will look and feel strange.

The mouth is a mobile and expressive feature that can convey every emotion from anger to happiness. It is a great revealer of character, and as such must be watched very carefully when timing the instant of exposure. There is often a point before a full smile is reached, or after it has nearly gone, when the lips have a pleasant expression that suits most people. The popular trick of asking the sitter to pronounce some short word which results in a half-opened mouth at the moment of exposure, serves a similar purpose.

With subjects where gravity and dignity are more suitable the photographer must wait for an expression of calm repose. The moods and emotions reflected in the human countenance are many and varied and the eye of the photographer must be trained to recognize them the instant they appear before he can expect the lens to record them.

Features. The type of sitter that the portrait photographer refers to as "photogenic" possesses features of such regularity and proportions that a satisfactory portrait of them can be obtained fairly easily, from any one of a variety of angles. But with most subjects one of the greatest problems in taking a portrait is to choose a viewpoint and pose of the head that will minimize or avoid often considerable irregularities of features and proportions. With a studio portrait which must please the sitter this is imperative, although in a pictorial character study for an exhibition it may not be so necessary. A woman usually has a definite opinion about which is the best side of her face, but the camera does not always agree with her.

If a line could be drawn down the centre of a face, it would be found, in many cases, that the nose was not quite straight, and that one side of the face was fuller than the other, while a line at right angles would show differences in level in the eyes and mouth; classical symmetry is rare.

One of the methods usually employed to overcome the appearance of a mouth that is not level is to turn the head away from the camera to a three-quarter or near-profile view, keeping the lower corner next to the lens. The same method is adopted when the distance from the outside corner of one eye to the corner of the mouth is greater than the corresponding distance on the other side. The longer side is kept next to the camera. Receding parallel lines appear to converge so in posing a sitter in the manner described, the lack of symmetry in the face is attributed to the normal convergence of such lines, and the face itself is seen as quite symmetrical.

A crooked nose is helped by photographing it from the side towards which it turns, and a broad nose is narrowed by taking it in three-quarter view with careful lighting to put the broader portion in shadow. A long nose or a weak chin is never emphasized by taking them

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

from above or with the head tilted down. With some sitters a sideways tilt of the head can make the angle of the jaw look too prominent, and when the cheeks are seen in outline, they must be compared to make sure that they are symmetrical, as a slight turn can make the face look lopsided.

In portraits of women the neck calls for special attention; too high a viewpoint makes it appear shortened, while the shoulders are made to look higher. The normal height of the camera, at the eye level of the subject, gives a satisfactory rendering and only slight variations of this are permissible, the more extreme angles being reserved for special subjects such as fashion photography.

With men, bald heads are made to appear more prominent by over-lighting, and the light on top of the head should be toned down by a soft-edged shadow from a small head screen, or by a piece of card held in an assistant's hand.

The edge of a beam of light, being softer than its centre, should also be employed whenever possible.

Where the sitter possesses an interesting or beautiful profile, it often makes the best portrait, particularly when certain irregularities can also be played down by taking the picture this way. The choice of the correct viewpoint in all such cases is most important and the movement of the lens an inch or two to one side or the other can have a critical effect on the final portrait.

The lighting effects are chosen both to give the best modelling of the features and to be in keeping with the type of subject. A round, full face, for instance, is made to look even wider and fuller by a broad, frontal lighting, but by lighting it from the side to give the head some bold, firmly-drawn shadows, it can be given a much improved form and structure. Thinner features, on the other hand, can be flattered with the more open frontal type of lighting. Lines of character are brought out in a face by a bold layout of lights and shadows made by the chief source of light.

Hands. The hands in a portrait are next in importance to the head as interesting and expressive features. Like faces, they vary in character and beauty. Some sitters are able to pose their hands easily at the suggestion of the photographer; those who cannot, or who have not good hands, call for a simple and unobtrusive treatment.

Certain views and poses are in any case to be avoided with all types of hands. The broad, flat view of the back or front of the hand to the camera is unpleasing because it looks larger and lacks the slenderness, beauty of line and tapering proportions of the hand viewed from the side. This essential difference can be seen clearly by comparing the effect of placing the hand at the side of the head, and placing it under the chin with the fist closed and the back of it to the camera. Unusual or strange views of the hands should also be avoided—e.g., the acute foreshortening of a hand pointing directly into the lens, fingers that are amputated, missing, or awkwardly interlaced.

Stiffness, both mental and physical, prevents good poses, and anything that can be done to give the sitter a relaxed, easy feeling helps to produce a better result. A lot of directions make the subject conscious of his hands; it is usually easier to arrive at a satisfactory arrangement by simply giving him something to hold or rest them on. In most cases, and in particular, with men, the simplest treatment with the hands in repose is the best, but where a woman has particularly beautiful hands, they can be given greater prominence by expressive poses that reveal their line and style to advantage. There are many possibilities for elegant and expressive arrangements in posing the wrists, hands and fingers of younger and prettier women in particular.

Children's hands should be left alone: their hands will look well in almost any position so long as it is arrived at naturally. If they are given something to hold, the object should be small, so that their hands can grasp it easily and be seen instead of being hidden by the object.

Backgrounds. The modern studio treatment of the background is generally simple. Painted landscape and rustic bridges belong to a bygone age. Head and shoulder portraits are taken against a plain background of black, dark grey, light cream, grey or white, and the variations in tone are produced by lighting. Even a white background can be made to photograph black if it is far enough behind the subject and all light is kept off it.

When sitters are taken in their own homes or offices, etc., the background is usually confused by a multiplicity of objects, patterns and furniture. As far as possible these should be arranged or removed to leave a simple setting for the subject.

Draperies often make effective backgrounds, especially for portraits of women and children, but the obtrusive patterns must be avoided and the folds should be carefully arranged and not sharply defined. The sheen of silk, or light through a gauzy film of muslin can lend a pleasing decorative effect, but it must always be kept subordinate to the sitter. In three-quarter and full length portraits there is more background in proportion to the subject than in head and shoulder portraits. Here, the judicious use of a piece of furniture, curtains or other suitable props, and variation of the background's lighting can help to create an effective composition and fill in the empty spaces.

Clothes. For the more formal type of portrait the appearance of the clothes, especially of women, needs careful attention. A dress that hangs in badly-arranged folds, or is creased and crumpled, or has a collar dis-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

arranged, etc., will not be acceptable to the sitter. So it pays the photographer to see that everything is in order at the sitting, to avoid the labour of correction on negative or print. Even a necklace must be properly arranged or it will mar the appearance of a well-groomed woman, and men's suits must be checked for bulging collars and creases in the wrong places. Service uniforms in particular call for great attention down to the last button. No such care is necessary with the easy, informal type of portrait which may even be improved by a suggestion of untidiness.

Make-up. Modern panchromatic emulsions give a smooth rendering to complexions, but occasionally more pronounced freckles and skin blemishes persist in showing. If these are objectionable to the sitter, they can be masked by the use of the correct make-up. This must be chosen to suit the type of lighting and sensitized material; ordinary make-up is rarely satisfactory. The use of make-up to create character or deliberately alter a face calls for special skill.

H.J.Wi.

LIGHTING

Controlled lighting in portraiture, as opposed to mere general illumination, is used for modelling—i.e., to create an impression of roundness and solidity in the two dimensional reproduction of the sitter's head and features—and to give a good likeness. Good lighting is not a matter of using a large number of high-powered lamps. Some of the best portraits are produced by means of very simple lighting, just as many of the greatest masterpieces of portrait painting have been produced by the use of just one simple light source, generally a diffused form of daylight.

Sunlight, diffused daylight, half-watt lighting and flash bulbs are the principal sources of light used in portraiture and there are many types of lighting that are capable of producing a first-class portrait.

Because of its convenience and portability, half-watt lights have become the most popular form of lighting for portrait photography. Such lights are easy to move into any position or any angle, to give front light, side light, and back light as required. Among the most popular light sources for amateurs are Photoflood lamps, which give a very intense light but have a much more limited life than the ordinary half-watt lamp.

These lamps are used in various types of reflectors and on a variety of stands which enable them to be placed in any desired position. The design of the reflector is important. A lamp with a narrow reflector will give a harder image than a lamp in a broader reflector, which tends to diffuse the light more.

Spotlights give a stronger and more concentrated form of light. They are useful principally for back lighting or effect lighting, but

MODELLING LAMP. One main light only produces hard and deep shadows on the side of the subject away from the lamp. The background tone gets darker farther away from the lamp.

can also be used as the main source for strong characterization or realistic skin texture.

Photoflood Lighting. The photographer making a portrait by artificial lighting has to decide how many lamps he will use, how powerful they must be, and where to place them. The commonest mistake is to use too many light sources with the result that one interferes with the other and there is no definite light or shade in the final picture.

A good lighting scheme may include the following basic units: the modelling light or main light, the general light or "fill-in" light, the background light, and the effect light.

Modelling Light. The purpose of this light is to form the actual light and shade areas in the portrait. All other lamps used are subsidiary to this light and are never allowed to compete with it.

Just as there is only one sun in the sky, giving one definite light and shade, so a good portrait produced by artificial light should have one principal source which produces a definite light and shade pattern.

General or Fill-in Light. The purpose of this light is to give an all-round illumination to the subject without throwing any definite shadows. Its object is to illuminate the shadows produced by the modelling light, and so improve the rendering of detail in these areas.

Photographic negative material cannot

USE OF REFLECTOR. A white card or other light-coloured area used as a reflector on the shadow side of the subject tends to relieve the blackness of the shadows.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

USE OF FILL-IN LIGHT. This lights up the shadows much more than a reflector can, and produces a more even light balance. The background also becomes more uniform in tone.

BACKGROUND LIGHT. A third lamp directed on to the background can give haloes and similar effects. The basic lighting balance on the subject itself is not affected.

accommodate itself to extreme contrasts in the same way as the human eye and deep shadows in which there is still detail discernible to the eye can frequently appear as blank areas on the negative. So there must always be sufficient general light to give the shadows the necessary detail.

Much of the general lighting can be provided by reflection from the surroundings. If the sitter is placed in a room where there is no daylight and where the surroundings are fairly dark, when the main source of light is switched on the shadows will appear extremely black and the whole lighting effect will be harsh and contrasty. On the other hand, if the walls of the room are white or light the shadows will appear very much softer and more luminous.

The most convenient way of producing the necessary general light is by a second lamp placed at a greater distance from the sitter than the main or modelling light. It may be used direct, or turned to shine on a wall or a white screen to light up the subject indirectly. Great care must be taken that this second source of light does not throw any shadows on to the face. Alternatively, instead of a second lamp, a reflector consisting of a white screen or sheet can be used to give the necessary illumination of the shadow areas.

A room in which there is daylight, particularly if it has light walls, can also be an ideal location for making a portrait, because the diffused daylight reflected from the walls provides an excellent type of general or foundation light. The window blinds or curtains can be opened or closed so that just the desired amount of reflected light is available. This method of lighting makes a separate fill-in light unnecessary.

Importance of Shadows. The power and distance of the fill-in light must be such that the shadows are neither too black nor over-illuminated. Too much general light weakens the shadows and destroys all the depth and roundness of the subject so that the resulting portrait looks insipid and lifeless. If too much fill-in light is used a portrait can be devoid of shadow altogether. This effect is sometimes produced deliberately to create a high key effect. Again, if the fill-in light is incorrectly placed, rival shadows can be produced which spoil the necessary positive character of the lighting.

An excellent way for the beginner to train his eye in the use of artificial light is to practise on a plaster bust, or a display head used for showing off hats in shop windows. In this way he can experiment without tiring his sitter. He should also study the lighting of leading portrait photographers and painters.

Background Light. The background light has a number of possible duties. It may simply be used to brighten the tone of the background where it is much darker than the subject by reason of its greater distance from the main light source. It may also be used to "kill" the shadow of the subject cast on the background by the modelling light. Or it may be used locally on the background to produce intentional differences of light and shade to complete the composition of the picture. It can consist of a half-watt lamp or a spotlight which is projected from behind the sitter or from the side on to the background from a position in which the source does not show in the picture. In such a case the sitter must be a little distance from the background. Illumination of this type helps to detach the model from the background. It may also be made to produce various patterns of light and shade according to the photographer's individual ideas.

It is a fairly common practice to illuminate the part of the background behind the darker side of the model leaving the part behind the lighter side of the model in shadow so that the subject stands out by contrast on each side. By shifting the background light, it is just as easy to allow the darker tones of the subject to merge gently into a dark area of the background. When using a plain neutral background, a background light can add a valuable play of light and shade to relieve an otherwise monotonous grey area.

Effect Light. The effect light is popular for the production of what are known as glamour portraits. In its commonest form it consists of a spotlight or half-watt light directed on to the sitter from the rear, producing a kind

of halo, or a rim of highlight. One or more such light sources may be used, and usually the more forceful the light, the more glamorized the portrait.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Effect lighting can also be used for emphasizing the contours of the profile, but it must never be allowed to shine on the face generally because it can easily ruin the harmonious lighting of the modelling light. Again, if it shines on existing highlights, they become over-exposed and will print as blank areas in the finished portrait.

Lighting Styles. Broadly speaking, there are two principal styles of lighting in portrait photography: dramatic lighting and classical lighting.

Dramatic lighting is the type of lighting which has been popularized by the movie picture and by the advertising studio. This consists of the use of a great deal of effect light, both on the sitter and also on the background.

Classical lighting is the type of lighting favoured by the great masters of traditional painting. It consists of only one dominating source of light giving a co-ordinated pattern of light and shadow without "effects".

Dramatic lighting is popular today, both in private portraiture and in commercial photography. Classical lighting may be less fashionable, but it is more suited to sympathetic characterization.

Lighting the Sitter. The standard approach in lighting the sitter is to start with one lamp. This is switched on and the effect of the shadows is studied. If these are too heavy for the type of portrait in view, the second lamp or general light is switched on and moved backwards and forwards until the shadows caused by the main light are sufficiently illuminated. The higher the main light, the longer the shadows under the nose and eyes of the sitter. When the main lamp is moved to one side of the sitter it will leave one side of the face more in shadow than the other. As the photographer moves his main light into different positions to achieve the lighting best suited to his sitter, the position of the fill-in light must also be altered so that the shadows are kept illuminated.

USE OF EFFECT LIGHT. A fourth lamp completes the lighting set-up by adding highlights to the hair, or, from a lower level, producing a rim of light around the subject.

Every sitter calls for a different arrangement of the lamps to suit his or her personal character and this offers tremendous scope for individual expression in manipulating the lighting. Diagrams and examples can provide only a rough guide. The beginner must learn to see photographically: experience alone can develop his feeling for the correct lighting. When he gains this he will instinctively place the lamps in the right position to give the best result for each type of sitter, without referring to diagrams.

The form of lighting which will always give a good likeness is a simple top-front-side-light, but there are many variations to it. It is impossible to lay down any hard and fast rule; the final arrangement is always a matter for the photographer.

Except for special effects—e.g., high key—the main light should never be at the same level as the sitter and shining exactly from the direction of the camera. This arrangement produces shadowless and flat lighting. A main light placed below eye level gives an unnatural type of lighting that is generally not suitable for straight portraiture, although it is sometimes appropriate when taking stage photographs of actors or actresses.

Generally speaking, a good starting point for lighting experiments is with the main light shining down at an angle of roughly 45° on the sitter, and 45° to one side of the camera-subject line.

The character of the subject is brought out by the shadows, so the weaker the fill-in lighting, the stronger will be the impression of character.

A soft general lighting with few or no shadows tends to idealize the subject. When thit effect is desired, well diffused frontal lighting some distance from the camera is employed. The nearer the lamp is brought to the sitter, the stronger the lighting becomes and the more it tends to emphasize heavy, rugged and male characteristics. So when photographing women a softer form of lighting employing diffusing screens is appropriate, whereas with men a stronger type of lighting is more suitable.

Full Lengths and Groups. In a portrait of a full length figure, it is important to have the main light high enough. Lighting that would give a good top-front-side-lighting of a seated portrait would, if used at the same height for a full length standing portrait, give an illumination too near head level. Some lighting stands, particularly those sold for amateur use, will not extend sufficiently high. The remedy is to get an assistant to hold the lamp at the correct height. In such portraits it is also important to remember that the lamp should be far enough away from the sitter to illuminate the whole of the figure. With a head and shoulder photograph this point is not important because the main lamp light may be anything from 4 feet to 10 feet from the sitter and still give

excellent lighting. This distance is much too close for a full length portrait.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Artificial light falls off in strength rapidly as the source is moved away from the model. A lamp moved to twice the distance away from the sitter—say from 2 yards to 4—would not require double the exposure but four times. So figure work calls for very much more powerful lighting and when working with full length portraits it is often an advantage to use two or three modelling lights in a vertical row to cut down the exposure while ensuring that the whole of the figure is evenly illuminated. With groups too, it is necessary to move the lamps farther away and allow extra exposure.

One Lamp Only. There is no hard and fast rule about the number of lamps needed for a portrait photograph. Excellent portrait studies can be secured with one lamp only.

When there is sufficient general daylight in the room, then a single lamp can be used. The artificial light will then serve as the modelling light and the daylight as the fill-in light. In rooms with light walls and with windows in more than one side of the room, one lamp can be made to give excellent results. The lighting is best arranged so that the shadow side of the model receives the direct daylight. On the other hand, if there is a strong source of daylight, the model can be brought quite close to the window, and the daylight used as the modelling light, while the Photoflood lamp is used to illuminate the shadows formed by the daylight. But nearly always it is more satisfactory to use artificial light as the modelling light and daylight as fill-in light.

Sometimes the subject can be placed so that the daylight from a window comes from behind and a little to one side. This arrangement creates an attractive backlight effect. The effect can be intensified by bringing the model nearer the window, but if this is overdone it will overpower the main light and the highest effect lights formed by the daylight will be so dense on the negative that they will print white.

A single lamp can also be used with a reflector to light up the shadows where there is no daylight available as the fill-in light. An additional backlight effect can be obtained by using a mirror from the rear of the model to reflect back the main light as an effect light, to illuminate the hair or the contours of the face. Thus, even a single lamp offers a selection of lighting arrangements by which good portraits may be made.

Two Lamps. When there are two lamps available, one is used as the main light, and the other as the fill-in or general light. If there is some daylight available but not enough to light up the shadows, the second lamp may be used to augment it. If the daylight in the room is strong enough to provide all the general lighting, the second lamp may be used as an effect light placed behind the model and a little to one side so that the light comes more or less towards the camera.

The second lamp may also be used for illuminating the background, being placed so that it shines from behind the model on to the wall. It may equally serve as a combined effect and background light. This is done by placing the lamp a little behind the sitter as it would be if it were serving as a background light but turned slightly towards the sitter so that part of its rays outline the model's head and part fall on the background at a slant.

Three Lamps. When three lamps are available it is usual to employ one as the modelling light, one as the fill-in or general light in the absence of daylight, and the third as a background light or to backlight the model. This lamp may also be made to operate as both a background and effect light as already described above.

If there is enough daylight for general lighting, the lighting set-up might be: one lamp as the main light, the second as an effect light, and the third as a background light. Or a double effect lighting might be arranged by having a lamp behind the model on each side. Or the background might be illuminated by having one or both of these effect lamps shining partly on the background at a slant.

Four Lamps. If four lamps are available one lamp might serve as the modelling light, the second as the fill-in light, the third as the effect light, and the fourth as the background light. With sufficient daylight for general lighting, the fill-in lamp could be dispensed with and used as an additional backlight effect. When photographing a group of four or five models two lamps can often be brought close together to provide the modelling light so as to give a bigger area of illumination and at the same time to cut down the exposure. In this case the third lamp could be used as the fill-in or general light and the fourth as background light or a backlight effect.

Often one lamp is used as the modelling light, one as the effect light on one side, another as a fairly high top effect light on the other side of the model. This type of lighting is particularly useful for lighting up blonde hair which has a tendency to come out darker than it really is under ordinary front or side lighting. The remaining lamp could be used for the background, or as the fill-in light.

Every position and face requires a different arrangement of the lamps. If the lamps are in a correct position for a full face or three-quarter face portrait, they must be readjusted if the face is moved to profile position otherwise the profile will be wrongly illuminated.

Lighting the Profile. What has been said above applies to full and three-quarter views of the face. The profile is best illuminated so that the main source of light comes from between the profile and the background either illuminating the profile or the contours of the profile, or shining across the contours so

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

that the near side of the face is illuminated with a patch of light and the remainder of the face is in deep shadow.

Flash. Satisfactory portraits can be made with flash bulbs. The disadvantage of this form of lighting is that unlike half-watt lighting one is unable to see the net result of the lighting before making the exposure. After some actual trials, however, backed by a thorough knowledge of half-watt lighting, the photographer can predict with near certainty the effect of any arrangement of flash bulbs.

Cameras today are mostly sold with an attachment for a flash bulb unit on the top or the side of the body. This by itself does not give satisfactory portrait lighting because it produces no shadows, and the result tends to be flat. In practice a larger size bulb than would be used for flash-on-camera is connected to an extension lead and used to provide the main light. The flash bulbs are, in fact, placed more or less where the ordinary half-watt lighting would be.

A broadly diffused general lighting can be created by "bouncing" a flash off a white wall or ceiling.

Sunlight. Much good portraiture is done with sunlight alone.

Low angle or slightly diffused sunlight gives the best results; high midday sunlight in summer is normally too harsh. Fill in light for the shadows is given by a white card or sheet used as a reflector. A small flash bulb may be used to illuminate the heavy shadows, but the technique must be used with restraint or the shadows become over-illuminated and the whole effect of sunshine is lost.

Flash bulbs are also useful out of doors for illuminating the camera side of the subject in against-the-light effects. On a dull day a flash bulb will give an impression of sunlight out of doors if it is fired from above and to the side of the subject.

Diffused Light. Diffused daylight from a window, with a white card as a reflector, makes a satisfactory lighting set up for portraiture. In this case as the light source cannot be adjusted, the sitter must be moved into the position that gives the most favourable lighting angle. If the window has curtains or blinds these can be opened or closed to control the area and placing of the light falling on the sitter.

When a white card is used as a reflector either indoors or out of doors it is important not to bring it so close that the depth of the shadows is so low that the result will look unbalanced.

A.M.

TECHNIQUE

When the subject has been posed and the most suitable lighting arranged, the final important phase is the actual technique of producing the photograph.

Camera. Studio cameras are usually half or whole plate size with a square bellows of long extension, allowing lenses of long focal length to be used, and a ground glass screen on which to compose the picture. The back of the camera should have side and back-swing movements. The lenses can be from 12 to 20 ins. focal length; used on a quarter- or half-plate they give a head and shoulders portrait to fill the frame without going too close to the subject, thus avoiding distortion. The relatively small depth of field of these long focus lenses requires a stop of f 5·6 to f 11 to give good definition on important parts of the subject.

A really solid studio stand is necessary to hold the weight of this type of camera and lens. It should be either of the central pillar type with a platform on top, or have a platform mounted between two vertical columns. The stand should be designed to allow the camera to be tilted, raised and lowered, and the whole apparatus should move easily on castors. The shutter is often behind the lens and should be silent. It is usually operated by a bulb and the photographer judges the exposure, although some makes can be pre-set to give the required exposure automatically.

Many successful photographers of children use a studio camera, but for this purpose the miniature or miniature reflex camera with quick focusing and automatic film transport is a very suitable instrument. The mobility and unobtrusiveness of the smaller camera enable the photographer to secure pictures with a spontaneous, unposed look. Excellent portraits of adults can also be taken with a miniature, using a long focus lens for close-ups.

Focusing. In the early days of portraiture lenses of the Petzval type, which gave soft definition except in the centre of the field, made it necessary to focus on the eyes, nose and mouth, leaving the rest of the head softly defined.

This gave a very pleasant effect of roundness, and present-day photographers using an anastigmat do this by selective focusing at a stop that avoids too great a depth of field. The ability of the modern anastigmat lens to give critical definition and show the texture of the skin and every line and wrinkle is exploited by some photographers to achieve a more literal and realistic treatment.

Negative. The miniature camera uses rolls of film, but for the studio camera there is a choice of plates or cut film. The latter has many advantages, being lighter, unbreakable, and less bulky than plates. Some panchromatic emulsions of high speed in artificial light, owing to their great red sensitivity, make the skin look like plaster, the lips pale and blue eyes unnaturally dark. A film of medium speed gives better flesh tones and finer grain.

Over-lighting, over-exposure and over-development are the enemies of good modelling. After a suitable balance of lighting has been secured by a few trials, the production of a good

negative should present no difficulties, so long as exposures are kept within fairly narrow limits and the time and temperature of development are standardized.

A good negative is the halfway stage in making a print of fine quality.

Retouching. As some retouching is necessary in professional studio portraits, the image of the head should be at least 1½ to 2 ins. high. The once popular smooth, empty faces with all lines of character removed are fortunately rare now, and many of the best modern portraits are made from unretouched negatives.

Print. The key of the picture, high or low, and the contrast, soft or bold, in relation to the type of sitter and the depth of print are important factors that can be altered to control the final result. The size and position of the image on the enlarging easel and the final trimming of the print can be used to vary the composition. A successful portrait, however, is a work of art and not merely of technique, so that it is not possible to lay down set rules on the subject. The nature of the subject and the individual taste of the photographer should decide the treatment. H.J.Wi.

PORTRAITURE AT HOME

Today, when fast emulsions have made portraits of people by ordinary room lighting a simple matter, the possibilities of this method of approach are not commonly realized. So many photographers nowadays think that a portrait cannot be really effective without elaborate lighting effects in a proper studio. Yet it is in their homes that people and children are to be found in their most characteristic activities and intimate moods. It is there that we get the authentic background that gives the key to their interests and outlook. The comfortable lived-in room, too often looked upon as merely a poor makeshift studio, is an infinitely better place for making true character studies than a studio can ever be. It should be left as far as possible undisturbed; to rearrange it is to destroy its authenticity.

The Best Camera. The camera must be quick in action and have a reasonably fast lens—*f* 3·5 at least—and a fair selection of shutter speeds, the slower ones being especially desirable. The more foolproof and automatic the camera is the better, so that more attention can be given to the subject. Quick and easy focusing is most important, especially for fairly close-up pictures of moving children; and portability, so that the level and angle of approach can be rapidly changed. Therefore a small reflex or coupled rangefinder camera is indicated.

Coupled rangefinder cameras with interchangeable lenses would seem the ideal, but, for taking moving subjects at fairly close range, many people claim that a focusing screen is quicker. Again, the eye-level position makes the camera more conspicuous and alarming than one held more casually at a lower level. Also, with a camera held to the face, it is difficult to converse with the sitter; with a reflex it is easy and also possible to take unexpected shots.

Camera Stand. The use of some form of support is often necessary when the lighting is too weak for fast exposure. This is unfortunate, because it makes the small camera almost as immobile as the traditional studio outfit.

The perfect camera stand does not exist; the nearest thing is the tripod with adjustable centre pillar, although this does not come down low enough for taking children at their own level on the floor.

Something home-made is generally the answer—e.g., a broomstick firmly held in a heavy base and fitted with a small sliding and tilting platform, held at the desired level by a suitable screw-clamp.

Lights and Reflectors. Though it is always wise to make the best of the existing lighting in order to preserve natural atmosphere, it will often be necessary to amplify or modify it considerably. To be prepared for all emergencies some sort of portable reflector is needed, a few Photofloods for use in ordinary light sockets, and one or two larger lamps on adjustable stands (with plenty of flex).

A synchro-flash outfit that can be used at some distance from the camera is another satisfactory type of light source.

The portable reflector need not be large—if it is it gets in the way; a piece of white oilcloth such as is used for table tops is very suitable. It should be about 3 × 4 feet, attached to two laths so that it can be rolled up when not in use; there should be some sort of collapsible stand to hang it on. It is an advantage to have some arrangement for holding the reflector at an angle.

Reflectors are easy to improvise, e.g., from a folding screen or clothes-horse with a white sheet draped over it.

Mirrors give a more directional lighting and are especially useful for backlighting effects but care must be taken not to reflect any light straight towards the camera lens.

Portable lamps should have heavy bases so

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DAYLIGHT INDOORS. Left: *The light is often better in an upstairs room, as there is less obstruction from trees, etc., outside the window.* Centre left: *The farther the subject is from the window, the less light reaches it. The lighting also becomes softer.* Centre right: *The lower part of the room receives more light than the top—an important point when taking full-length portraits.* Right: *A reflector is usually desirable for indoor shots so that the light is well distributed and is not too contrasty.*

that they are not easily knocked over. The flex should either go through a hook or eye at the base, or be suspended overhead and clipped or hooked on to the picture rail or some other suitable anchorage. One lamp should preferably have a fairly large matt reflector, fitted with some form of detachable diffusing screen; the other reflector can be smaller and have a polished surface to provide a sharper, more concentrated light.

Flash has obvious advantages: it is powerful and portable. The disadvantage is that its effect cannot be studied beforehand and the result may show unpleasant surprises in the way of cast shadows and glaring reflections in spectacle lenses and other polished articles. Also, in its most common form—i.e., permanently attached to the camera—it gives a low flat lighting that tends to destroy modelling.

Perhaps the most useful method of employing flash in at-home portraiture is to bounce it from wall or ceiling. This floods the whole scene with soft secondary light which brings out shadow detail that would otherwise be lost.

A similar effect, though hardly as good, can be got by heavily diffusing the light with, say, a couple of handkerchiefs. This device is also useful with flash-on-camera as a method of controlling light intensity to get the right balance with the rest of the lighting.

General Lighting. It is better to look for an appropriate natural setting first and then decide if it is getting enough light for reasonably short exposures rather than to look for a setting where the light is right. There is no such thing as right lighting or wrong lighting in the absolute sense; any kind of lighting may be suitable in that it may be appropriate to the general scene and part of its mood or atmosphere, although it will not necessarily be possible to take photographs by it. However, with a fairly static subject it should be possible to catch the sitter with a characteristic pose and expression quite easily at 1/10 second or perhaps even ½ second.

When exposures must be short, the best thing is to look for light places—i.e., light rooms with the more high windows the better. (If they are in more than one wall, better still, for this will make it possible to get interesting cross-lighting effects.) Upstairs rooms are often better than lower rooms, where the light is apt to be obstructed by trees or buildings. Light-toned walls are to be preferred because they reflect a soft light throughout the room, whereas dark surfaces absorb light, and make for heavy shadows, long exposures and contrasty lighting.

The lightest place is always on the floor near the window and this is the ideal spot for taking children at play. But the light weakens rapidly as you move away in the room and it also becomes softer in character—i.e., the boundary between light and shadow becomes less marked. The upper part of the room always receives less light than the lower and this has to be borne in mind when taking grown-ups at full length, for, unless they are close to the window, the feet will get noticeably more illumination than the head. All this can be easily checked with an exposure meter.

Mixed Lighting. When using electric lamps and daylight together it should be remembered that, though to the eye the artificial lighting may apppear the stronger, the daylight may have the greater effect on the film. The result of any particular combination can only be foretold by practice. Judgement is easier if the excess of red and yellow, which causes the lamp-light to appear so strong to the eye, is held back a little by a pale blue filter in front of the lamp. A circle of pale blue gelatin (described as "daylight blue") such as is fixed on stage lights in the theatre can be used. It should be large enough to filter the direct light from the bulb, but should not fit flush over the lamp reflector or it will over-heat.

The comparative values of artificial light and daylight can be worked out by means of tables and an exposure meter, but in practice past experience will be found the best guide.

Sunlight Indoors. Sunlight effects indoors look most attractive, but the contrast between light and shadow is usually so extreme that the film cannot handle it unless the shadows are flooded with fill-in lighting. It will only very occasion-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

THE LIGHT FROM ONE WINDOW. 1. With the window more or less central in the wall, the sitter should be to one side of it, and a matt reflector on the shadow side. 2. Dead front lighting yields flat results; the more the camera moves round, the more shadow becomes visible, until behind the subject the camera sees only a silhouette outlined by light. 3. A mirror behind the sitter can act like a second window. 4. The mirror can be placed to provide secondary side lighting.

ally be possible to do this with a white reflector placed near enough to the subject for it to be able both to receive direct sunlight, and reflect it in the right direction. Sometimes a mirror will provide the right sort of reflection if it can be kept out of the sun. Direct sunshine reflected from a mirror would be much too fierce and probably also patchy.

The simplest way out is to supplement the fill-in lighting with one or two lamps or, perhaps better still, flash. If there is a light wall not too far away the flash can probably be bounced; if used direct it will have to be a fair distance away or suitably diffused. A photolamp can be used at fairly close range, and preferably diffused to avoid too definite secondary shadows. Two, close together, both diffused and rather farther away are likely to give an even better effect, which will look more like normal reflected light. Usually it is best to let the fill-in light come from the direction of the camera.

Exposure should now be set for the sunlight and will usually turn out to be very much less than might be expected.

Artificial Light Only. When there is no daylight at all, the effect of normal room lighting can be achieved by bouncing a soft flood of light from walls or ceiling with either lamps or flash. If short exposures are required, lamps or flash can be used direct and the general balance of light corrected by putting small Photofloods in the light fittings. This will preserve the natural appearance of a room, when using artificial lighting only, but care must be taken not to make conspicuous shadows and not to take away all the characteristic shadowy corners.

Unless Photofloods are used with restraint the home atmosphere is bound to go, so dramatic or fancy lighting effects should be avoided. For adults one lamp will generally be enough for the main lighting and a second one for shadow illumination. But in a large room it is sometimes wise to light up a distant part of the scene, which would otherwise come out too dark, and so make the subject stand out in perspective.

Most of the best pictures come from taking chances, and accidental effects of lighting often prove much more fascinating than those which are carefully planned. But it is never a good idea to place two lamps at equal distances from the subject, so that the one entirely cancels out the shadows cast by the other; this produces a really ghastly effect.

Light on the Background. When experimenting with the lighting on the sitter and trying various camera angles, the changing background should be taken into account. From one angle it may be the dark corner next to the window, then with a change of camera position a fairly well lighted wall comes into view. These variations

BAY WINDOWS. With the subject actually placed in the bay window, additional lighting effects are possible. 1. If positioned to one end of the bay, the subject receives a combined front and side light against a window background. 2. Placed in the middle of the bay, the subject is lit by double side lighting. The sitter should not be quite in the middle, or the light becomes too uniformly balanced from both sides. The reflector should be strongly directional as the shadows facing the camera are quite heavy.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

INDOOR BACKGROUNDS. 1. With the subject to one side of the window, taken against the corner of the room, the background gets gradually darker and contrasts against the light side of the face. Movement of camera includes more or less of dark corner. 2. If the subject faces the window, the profile will again stand out against the dark wall. 3. If no reflector is available, moving the subject farther into the room will soften the lighting, but also increase the exposure required.

in tone can be exploited, together with various items of geography such as the position of doors, furniture, pictures, etc., in providing suitable background effects. In the shady parts details are subdued, in the lighter ones they will be more noticeable. Thus the placing of the sitter and choice of camera angle can more or less determine the emphasis given to the features and character of the surroundings.

Special attention should also be given to the effect of each lamp on the background, which in a small room may have to be shielded in some way from direct light to prevent it from becoming conspicuous.

Furniture and pictures can easily be overstressed and there may be awkward heavy masses of shadow or bright reflections from polished edges.

The variations in the tone of the background can be largely chosen to suit the effect of light on the sitter. A dark corner can be used to enhance the effect of strong side lighting, a paler tone will go with a more delicate effect, and so on. Often the background changes gradually as the camera is moved, but sometimes even a very slight shift may bring in view a light patch which may be just what is wanted to show up the shadow side of the model.

There are occasions when the whole setting should be clearly and sharply defined in detail, but where it has no special value or is positively inappropriate it must be played down or completely suppressed. Leaving space behind the sitter helps to put the background out of focus —perhaps the most effective method of suppression. In this way, when taking a close-up portrait, there is no difficulty at all in reducing a fussy background to a series of indefinite shapes and blobs, which can suggest perspective and local atmosphere without really picturing anything in recognizable form. It is helpful if the effect can be studied on a focusing screen so that the abstract shapes may be arranged to the best advantage, and the lighter parts perhaps used to silhouette the contours of the subject on the shadow side. A very slight change in the angle of approach will often make all the difference.

Managing the Sitter. It is only on rare occasions that the subject looks right from the start; generally it is necessary to do a certain amount of staging. This does not mean starting with a rigid preconceived plan, but the subject will often have to be persuaded at least to move to a suitable place.

The methods adopted should be indirect. A definite pose should never be asked for; it will invariably look wrong. A better approach is, "How would it be if you sat there and went on with your knitting?" And, obviously, to ask for a smile merely results in a self-conscious smirk. The only way to get a genuine expres-

TWO WINDOWS. 1. Two windows in the same wall can be used for side-front and side-rear lighting respectively, with the sitter between them. 2. If one window is covered with net curtains, it can serve as background and at the same time provide a soft back light. 3. Two windows at right angles can serve as main and fill-in light. Varying effects obtainable by camera movement. 4. Movement of the subject adjusts the relative light on it from the windows.

sion, whether amused or serious, is to say something appropriate, do something or create conditions which will produce spontaneously the characteristic subtle turn of the head and look in the eyes.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Speed is necessary once the desired effect has been achieved, but the preparatory work should be unhurried. The sitter must be made to relax first.

Unforced conversation helps and an intelligent friend, who can make occasional appropriate remarks, is the ideal foil. But the spectator who makes comments about the sitter's expression, clothing or hair should be avoided at all cost.

Nearly always the best way of achieving naturalness is to get the sitter to do something—to move rather than just sit. There is no difficulty with children: they may show a little curiosity about the camera at first, but it wears off if they are encouraged to play about. The photographer should be friendly, and treat children as equals, answer their questions honestly and, if necessary, let them look into the camera. He may even enter into their play, although as far as possible he should remain a detached observer. Parents can be useful here, but not those who fuss about clothes and make suggestions at critical moments.

A small infant can be simply put down in a light place; older children can be induced to play near the window if they are told quite honestly why they are wanted to stay there. With a child that has got to the stage where it crawls rapidly from one end of the room to the other there is nothing for it but to follow it round and hope for the best. Patience, an easily moved lamp, and constant adjustment of shutter or stop are the ingredients of success in this branch of at-home portraiture.

The photographer should never allow his sitters to "dress up", or be dressed up: it will make them more than normally self-conscious. Ordinary, everyday things that have had some wear acquire character of their own and look more natural.

Groups. It is not easy to arrange a group in such a way that it does not look posed: the only possibility is to bunch the people roughly and leave them awhile to relax into something approaching naturalness. They should be encouraged to talk or, if there are not too many of them, to look at something, play cards, have tea—anything at all that breaks the tension. It is inevitable that there should be someone with his back turned to the camera, but even this can add to the natural appearance, and a back view can sometimes make a very good portrait. It is always wise to take very many shots for it is only occasionally that the whole group will look just right at the same moment.

Children are on the whole perhaps easier to manage; they can often be induced to play amicably together for a while, and, if later a fight develops, even that may make an excellent picture. Most trouble arises if the children vary greatly in age and interests and one of them is at the roving stage.

It is rarely possible to get satisfactory lighting over a group of more than two or three; unless the windows are exceptionally high the light will always be uneven. This can be put right by augmenting the light source with Photofloods or flash. Generally a soft, even light, slightly from the side and fairly high, will be found best, and it is important to see that no member of the group is too much in shadow.

General diffused shadow illumination is almost essential.

Sharpness. With indoor light it is never possible to stop down very much, but lack of depth at wide apertures has its advantages when dealing with unsuitable backgrounds. But the portrait itself need not necessarily have over-sharpness either,

One part may be emphasized sharply and the rest allowed to go more or less out of focus. The out-of-focus image can still be extraordinarily expressive.

For instance, in photographing a sitter with unusually expressive hands or gestures, the hands might be focused sharply with the face slightly softer; or the focusing might concentrate on the character of the face and let the hands be a mere suggestion to give point to the posture or emphasize the rhythm of a movement.

Again, in a close-up head, there is no reason why a part should not be allowed to go out of focus. This will in fact help to give the portrait a three-dimensional quality. Such treatment is of course a matter of taste, but it should be stressed that over-all sharpness is not necessarily always a virtue.

The other kind of unsharpness due to movement of the subject itself often results in surprisingly live and expressive pictures. Negatives with blur of this kind should never be scrapped without first making a trial print, for they may turn out to be more expressive than the technically perfect exposures. It is always possible that among several blurred negatives of a lively child there may be a masterpiece. The fact that it was obtained by accident should make no difference. H.v.W.

Colour. For shooting in colour, there must be sufficient available light. Colour transparency material should be exposed correctly, so there is no question of under-exposing. Further, it is not possible to use any combination of light sources, as with black and white material, and any fill-in illumination must be of the same colour temperature as the main lighting.

PORTRAITURE OUTDOORS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Nowadays daylight portraiture has by common consent come to mean largely outdoor portraiture. With artificial light, the photographer has at his disposal a variety of lighting effects which he can alter at will; out of doors he has to make the best of the existing lighting conditions. On the other hand, an infinite choice of scene is available in the open and there is no end to the outdoor activities which provide opportunities for portraying people.

The vital qualities of outdoor portraits are naturalness and simplicity; there must be no forced artificial posing. While one may get away with such effects in a studio, outdoors they become conspicuous and insincere. Because of this need for naturalness, outdoor portraiture comes quite near to snapshooting with the difference that it still needs careful planning and technique.

None of the fundamental principles of portraiture may be neglected; one must not go nearer to the subject than the camera will focus, nor take such extreme close-ups with supplementary lenses that the features nearest the camera, for instance the nose or chin, become distorted. Arms and legs must not be stretched out towards the camera.

It is important always to give subjects something to do even if it is only resting on the sand. And their hands should be occupied; they should not just stand somewhere with their arms dangling helplessly.

Backgrounds. One sure way to spoil an outdoor portrait is by selecting an unsuitable background. Unless the background is deliberately made part and parcel of the picture, as for instance in a portrait taken in a boat or car, the subject must be well separated from the background. And the background must not be fussy and distracting, nor should it be ugly—a gasometer is no setting for a glamorous young woman. Trees, bushes and brick walls are popular but unsuitable backgrounds. Exceptions are when the sitter is in the sun and the background is in the shade. If bushes and trees form the background they should be very dense and not show patches of sky through the leaves and branches; light patches produce bright round circles on the print. The subject must be placed so that branches and other objects do not appear to sprout from the head in the finished portrait.

And when portraying one person, passers-by should not be strolling about at random in the background.

The best way to get rid of an unsuitable background is to take the subject against the sky; the outdoor effect is unmistakable and there is nothing to mar its simplicity. Other ways are to make sure that the background is completely out of focus or, with a head and shoulder close-up, to trim off the unwanted background altogether.

Sunlight. Strong sunlight is a much more contrasty light source than anyone would normally employ in a studio. It is unkind to any but very youthful complexions, and emphasizes wrinkles and rough or large-pored skin, simply because even the tiniest irregularity throws a strong though small shadow. The larger shadows thrown by the nose and chin are also strong and very dark, and so is the heavy shadow caused by a large hat brim. This high contrast is greatest when the sun shines from a cloudless blue sky and there is little scattered light to soften the shadows.

White clouds in the sky are very efficient reflectors and throw an appreciable amount of reflected light into the shadow areas, which greatly reduces the contrast and gives a more pleasing portrait. In such conditions there is also less contrast when the subject is placed in a wide open space where reflected light radiates from all sides.

A little light is also reflected from the ground. When the subject is standing on dry sand or snow, the ground reflects enough light to brighten all shadows to an almost ideal degree.

If nature will not help, some kind of artificial reflector must be contrived. It may be possible to place the subject near a brightly painted wall. While it may not be practicable to carry a

OUTDOOR PORTRAITURE. Left: *Overcast sky conditions yield very flat results without any modelling, or shadows.* Centre: *In dull weather a flash bulb can simulate the effect of sunshine, and has the advantage that it can come from any direction.* Right: *Hazy sunlight is the ideal lighting for outdoor portraits, as it casts soft shadows without excessive contrasts.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FILL-IN LIGHT OUTDOORS. Left: *Strong sunlight produces strong shadows and brilliant highlights. The lighting contrast may easily become excessive, especially for colour film.* Centre: *A reflector, such as a white card, casts light into too dark shadows.* Right: *A synchronized flash bulb can also act as fill-in light, and has the advantage of being more mobile and permitting wider light control.*

large, light-coloured board outdoors, a sheet of newspaper is perfectly efficient. Its effect can be clearly seen and a few experiments soon show the correct distance. It should not be so near the sitter's face that it cancels the shadows out completely or robs them of their modelling effect.

When the sun is slightly diffused by haze or light cloud, the lighting becomes very soft and ideal for outdoor portraits; contrast is low and shadows become faint and blurred, yet good modelling remains. This is, perhaps, the best lighting for colour and, with correct exposure, natural and pastel tones in the flesh rendering are almost assured—a result which direct sunlight will not yield.

Direction of the Light. The position of the sun in the sky determines the type of modelling of a portrait. Front lighting, that is with the sun behind the camera, can be effective with colour film but it is too flat with black-and-white material. There are no shadows and therefore there is no impression of depth. It is also the most uncomfortable position for the sitter, who will be hard put to keep from squinting or peeping through half-closed eyes; children certainly cannot be expected to keep a natural expression with the sun in their eyes.

Better modelling as well as less discomfort for the sitter is given by the well-known 45° lighting, that is with the sun still behind the camera but very much to one side. It also means that the light must shine down from above the level of the subject and, although the sun may be too high or low in the sky, a willing sitter can correct this simply with a suitable inclination of the head. That may even provide a better composition than an upright pose.

A completely all-round variety of lighting effects can be produced by portraying the sitter lying down—a very natural pose on the beach or in a meadow.

Partial or complete backlighting, with the sun more or less behind the sitter, makes for beautiful portraits. A rim of light, either down the edge of the cheek or in the hair, more than makes up for flat lighting of the shaded part of the face. The exposure must be calculated for the shadows. An efficient lens hood should in any case always be used; but if even that does not prevent the sun from shining into the lens with against-the-light shots, it may be possible to shoot from the shade of a tree or building, or a hat or book can be used to shield the lens if it is held high enough not to intrude into the picture area.

Without Sun. Very pleasing portraits can be taken without sunlight. In fact, when the sun is very strong and there are no means of illuminating the shadows, it is far better to place the sitter in open shade, such as that provided by a large building.

The light, although very diffused, will still give good modelling. Colour portraits taken entirely without sunlight tend to have a blue-green cast, which should be corrected by using a "warm" filter on the camera—e.g. a pink skylight filter.

Under a completely overcast sky the light becomes altogether too flat because it falls on the subject from all sides with almost equal strength, giving at the most only a faint shadow under the chin. In these conditions the sky is not a good background; among other drawbacks, irradiation may occur and blur the outlines. Portraits taken under a dull sky can be given more life and sparkle by printing on a hard grade of paper.

Flash. The compact and in some cases even pocketable flash guns, available for use with the synchronized shutters of modern cameras, provide the best means of overcoming the problems set by the existing lighting out of doors.

There are two distinct ways of using flash in daylight: to illuminate shadows in strong sunlight (fill-in flash), to act as modelling light on dull days (synchro-sun).

In both methods, a lighting ratio of about three or four to one between main light and shadows should be aimed at for both colour and black-and-white films. It is important to be quite certain of your personal version of the guide number which will depend on your working methods, flash reflector, develop-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ment and the type of negative aimed at. The guide numbers given by the flash manufacturers are usually valid for use indoors in rooms of average size and with light-coloured walls and ceiling. Outdoors it becomes necessary to apply a smaller guide number, the reduction corresponding to one or two stops.

Fill-in Flash. First find the correct exposure for the sunlit subject and set the camera controls accordingly, ignoring the flash. The guide number then determines the distance from the subject at which the flash (not necessarily the camera) has to be used.

Dividing the guide number by the stop gives the distance at which the flash will exactly balance the sunlight, whereas it must contribute only one-third. Therefore the guide number must be divided, not by the stop used, but by the figure corresponding to opening up two stops.

Example: sunlight exposure 1/50 second at *f*11. Set the camera controls accordingly. Correct guide number: 77. Divide guide number by *f*5·6 instead of *f*11 (two stops larger), i.e., 77 ÷ 5·6 = 14. So the flash must be used at 14 feet.

This ratio is correct with black-and-white film, but, with colour film which demands greater care in exposure, the fact that the flash illuminates the sunlit part of the subject as well as the shaded part must be compensated for by closing the aperture by half a stop for absolutely correct exposure.

If it is inconvenient to set up the flash gun at the distance dictated by the guide number, the light output can be reduced by hanging one or more white handkerchiefs over the bulb. Each handkerchief will roughly halve the light.

Synchro-sun. When using flash to produce the effect of sunlight on dull days great care is necessary because the background must necessarily remain dull and darker than the subject.

Over-lighting the subject by using the flash is one of the worst effects of faking in photography, and spoils the picture. A sunlit figure in front of a black open background looks unnatural, but as long as the correct guide number is used the degree of contrast is easily controllable.

Even so, in portraits it is preferable to make the picture a close-up with little background, or take it against the sky. In fact, the slight underexposure of the sky makes it darker (bluer with colour film) and therefore a much better background. Flash, in effect, can then take the place of a filter.

With this method, the daylight provides the fill-in light for the shadows thrown by the flash. So first determine the exposure for the existing light and set the camera controls accordingly, then, to subdue the daylight and achieve the necessary contrast, close the aperture by one stop. Now divide the guide number by the stop in use, and the answer gives the distance of the flash from the subject.

Example: guide number 77. Daylight exposure 1/50 second at *f*8. Set camera to 1/50 second at *f*11. Divide guide number by stop used—i.e., 77 ÷ 11 = 7. The flash must be used at 7 feet.

The ratio of main to fill-in light here appears to be 2 : 1 but this is not so, because the flash is additional to the prevailing light. This method, while satisfactory with black-and-white film, is therefore not so suited to the small latitude of colour material, for the absolutely correct exposure for the existing light plus the flash is difficult to determine. It varies with the quality and intensity of the prevailing light. Stopping down by half a number is a good average allowance to make.

Blue flash bulbs must be used with colour film, but electronic flash is suitable for both colour and black-and-white.

Films and Filters. All films are more or less suitable for daylight portraits. Ortho film is better for children and girls with good complexions and not too much lipstick. It gives good skin rendering but over-darkens lips and blemishes. Pan film is kinder to the not-so-perfect complexion. Slow films with their higher contrast are more suitable for male portraits, giving more vigorous tone rendering.

When taking portraits against a blue sky, it is necessary to darken the sky by means of a filter. A blank, white sky makes a very unpleasant background. With ortho film a light to medium yellow filter should be used; with pan, a yellow or yellow-green. The yellow-green is preferable because it gives skin a beautifully smooth and sun-tanned appearance. With colour film, a polarizing filter will, in certain conditions, darken a blue sky. H.W.

PORTUGAL. There is no photographic industry in Portugal, nor have Portuguese inventors or scientists made any contribution to the advancement of photography. A few skilled amateurs have designed and constructed their own cameras and enlargers, but none of their apparatus was intended for sale commercially. In fact, as recently as 1920, Portuguese professional photographers were still preparing their own photographic papers.

Nowadays all photographic apparatus and sensitive materials are imported from the principal firms in France, Germany, Great Britain, Italy, Switzerland and U.S.A. A large variety of cameras, accessories and materials is thus usually available.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Popular Interest. Photography is extremely popular in Portugal; it is a favourite hobby with many thousands of amateurs. Even in the remotest localities roll films are available, and this increasing enthusiasm can be attributed to the artistic temperament of the Portuguese people, combined with the brilliant light and the beauty and variety of subjects which the country offers. It is usual for people of modest means, who do not own a camera, to hire a simple model for such occasions as annual holidays, etc.

Professionals. Portrait photographers are to be found in most towns, and in Lisbon several workers rival the best foreign photographers in this field and have gained international recognition.

Excellent photographic coverage of social, sporting and political events is provided by a number of professional photographers. Lisbon and Oporto are particularly noteworthy for the high quality of photographic work performed in the scientific, industrial and artistic fields. The standard compares favourably with the level of achievement in other countries. Evidence of this fact is provided by some notable publications on the fine arts, also by those issued by government departments and private firms.

In Portugal as in other countries photography is much used in science and industry, particularly in the former. The ministries, departments of state and most of the large laboratories maintain their own photographic departments.

In industry photography is less widely used, though a considerable amount of work is done for documentary, record and publicity purposes.

The availability of high quality apparatus and materials and of the best foreign publications, together with the attractive displays in dealers' windows, enables workers to keep abreast of the latest developments and at the same time educates public taste. Photography can be said to have established itself as an essential element of the national life. The government itself encourages and supports it, notably through its tourist services.

Clubs and Societies. The following is a list of clubs, those with the largest membership being placed first: Foto-Club 6 × 6 (Lisbon); Grupo Câmara (the Camera Group) in Coimbra; Associação Fotográfica do Porto (The Photographic Association) in Oporto; Grémio Associação Fotográfica de Santarém (the Photographic Association) in Santarém. The first four have an average membership of 200. Amateurs throughout the country continue to form groups and clubs which enable members to submit their work collectively to the major international exhibitions abroad. Among such new groups are the Associação Fotográfica do Norte, at Oporto; the Associação Galitos, of Aveiro; the Arte e Sport, of Lisbon; the Sport Lisbon e Benfica, of Lisbon; and the Associação Fotográfica do Sul, of Evora. There are also many sports clubs and industrial and commercial enterprises which include photography among their activities.

Exhibitions. In recent years national and international exhibitions of considerable merit have been held in several Portuguese towns under the auspices of the amateur photographic clubs, which have done much to improve the technical and artistic quality of photographic work in Portugal. The average level of work is as high as in other countries in the forefront of photography, and the Lisbon International Salon is recognized as one of the finest in the world. There are few photographic year-books which do not publish photographs by Portuguese pictorialists of international reputation.

Amateurs and clubs regularly send in both individual and collective entries to the best international exhibitions held in other countries, and high awards have been gained in competition with leading foreign workers.

Every two years, an International Exhibition of Photographic Art, sponsored by the Companhia Nacional de Navegação (National Steamship Company), takes place in Lisbon. This outstanding event has been considered, from the beginning, among the best in the world. The annual International Exhibition of Artistic Photography, sponsored by the Companhia Uniao Fabril of Barreiro and the International Salon organized by the Sport Lisbon e Benfica, have also reached a high standard.

It is interesting to note that, although many amateurs are devotees of the modernist schools at present in favour, the majority prefer to go after typically Portuguese themes, and to treat them in the traditional pictorial manner.

Magazines. Few photographic journals have succeeded in maintaining themselves over a period of years; many have ceased publication after a short period. In spite of the value of such publications, Portuguese photographers generally prefer foreign magazines, which are superior and are on regular sale in Portugal.

Some years ago, during a period of increasing expansion of amateur photography, greater participation in international exhibitions and technical progress, the magazine *Objectiva* appeared. It was an excellent publication and succeeded in maintaining itself for a number of years, performing excellent service for amateur photographers. After its disappearance the magazine *Cinema e Fotografia de Amadores* was published: later came the *Boletim Mensal do Grupo Câmara* of Coimbra and a small magazine entitled *Fotografia*, which was well produced and had interesting articles. At present there are no photographic magazines produced in Portugal. Some years ago the first issue of the Annual *Almanaque Portugues de Fotografia* came out and was well received by the photographic public. A.Pr.

POSING. Technique of arranging people to be photographed in characteristic or pleasing attitudes.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Books: *Posing Patterns*, by L. E. Broome (London); *Posing for the Camera*, by H. Shepard and L. Meyer (London).

POSITIVE. In photography, a print or transparency showing an image composed of light (or transparent) and dark (or opaque) areas which correspond to the light and shade of the original image. In a colour positive, the colours of the image correspond to the actual colours of the original subject.

The term positive is also used in electricity to define a contact which has a higher potential of electromotive force than an associated contact (the negative).

POSITIVE LENS. Lens which is thicker in the middle than at the edge, having at least one convex surface. Also known as a converging lens, it is capable of forming a real image, i.e. one that can be focused on a screen.

See also: *Converging lens.*

POSTCARD. Standard size, 3½ × 5½ ins., of a picture-card for transmission through the post. Many millions of such cards are printed every year and all makers of sensitized materials supply bromide and contact paper either cut to this size or in continuous rolls of the correct width, and already printed with the standard matter on the back.

See also: *Postcard manufacture; Sizes and packings.*

POSTCARD MANUFACTURE. A few firms specialize in producing photographic postcards; these are sold as picture postcards in all the principal holiday resorts as well as other places of interest. The largest manufacturers can turn out a million photo postcards a week.

The photographs are procured by the firm's own staff photographers working to planned journeys and on continuous tour from May to September. The number of new and replacement photographs taken in a year depends very much on the weather and on features like changes in scenery, etc.

The Negative. The staff photographers work with half-plate size field cameras loaded with cut film. They send their negatives to headquarters at regular intervals for processing. At the factory the negatives are projected for detailed examination, and after the best have been selected, postcard-sized copy negatives are made on film. The original negatives are carefully catalogued and filed after the reduced negatives have been made. The cards are printed from the copy negative.

Printing. Because a single grade of printing paper is used for producing postcards, copy negatives must be standardized to a consistent opacity range. This procedure also prevents the original negatives from becoming damaged.

To make a postcard the following operations have to be carried out: exposure, developing, stop-bath, fixing, washing, backing (i.e. heading spaces for address and correspondence on the back), cutting to single postcards. These operations are generally nowadays performed as a set of sequential steps on bromide paper fed from a roll generally containing 1,000 feet of paper.

From two to four subjects are printed at a time. The copy negatives of the subjects are mounted in a frame which can be slipped into the exposing head of the machine, all the subjects being printed with one exposure. In the exposing head, the web of paper with a latent image is led to tanks containing the necessary processing chemicals for developing, fixing, washing, and bleaching and, if required, toning.

The web then passes over rollers set at the top of each tank and under rollers in the bottom of the tank. Typical times for each process: exposure ·03 sec., developing 2 mins., stop-bath ½ min., fixing 4 mins., wash, at least 20 mins. The web of paper with the subjects fully developed, fixed and washed is led into drying ovens through which it passes by a similar method of top and bottom rollers.

At this stage in some plants the web is reeled up again and later, as a separate operation, the paper may be glazed by being fed into a heated glazing drum whose glazing surface is generally highly polished stainless steel. There then follows the printing, by litho or letterpress, of the backer, and cutting into singles.

Variations that occur from plant to plant are in the number of subjects that are printed at one exposure, the width of the paper used, the speed of the process and the number of operations that are performed without handling or re-reeling the paper. Paper speeds vary from between 7 and 8 feet to over 30 feet a minute.

Picture Requirements. Commercial postcard printers are always willing to consider the work of amateur photographers. Negatives should possess good depth of field. Subjects are best chosen by considering as a picture just what a tourist would readily buy as a souvenir of a visit. The view should be above all readily recognized as local—i.e., it should include some familiar feature, building or landmark associated with the place. G.I.B. (B.K.)

See also: *Processing machines; Roll head printer.*

POSTERIZATION. Extreme tone separation can produce strong poster-like effects in as few as four tones, in which most of the image detail is suppressed.

For pictures in four tones, three separation negatives are required. Excepting the highlight negative, these are processed for extreme contrast to give negatives consisting of an opaque image on a clear ground—like a silhouette.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(Repeated duplication on contrasty films or plates may be necessary to produce the right type of negative.)

The Negatives. The highlight negative image covers only the highlight areas.

The medium tone image covers highlight and medium tone areas.

The shadow negative image masks everything but the deepest shadows.

The highlight, medium tone, and shadow negatives are then printed successively in order on the same sheet of printing paper, and in exact register.

Exposing the Print. The exposure through the highlight negative is the shortest. It should just be long enough to produce a light grey all over the test strip, but leaving the extreme highlights white.

The second exposure through the medium tone negative is longer. The image in this case protects the highlights and medium tones from further exposure, but allows a dark grey tone to print over the shadow area of the picture.

During the final exposure, the image of the shadow negative protects all but the deepest shadows, and these print full black once the whole print has been developed.

The final picture, therefore, has four tones: white highlights, light grey medium tones, dark grey tones, and full black shadows.

Five tones (including three greys: light grey just off white, medium and dark) may be obtained in the same way by using a fourth separation negative.

POTASH ALUM. Hardening agent used in fixing baths. Full chemical name, potassium aluminium sulphate.

See also: *Alum, potash.*

POTASSIUM ALUMINIUM SULPHATE. Full chemical name of hardening agent used in fixing baths. Also known as potassium or potash alum.

See also: *Alum, potash.*

POTASSIUM BICHROMATE. Potassium dichromate. Used in chromium intensifier and carbon, carbro, and gum-bichromate sensitisers.

Formula and molecular weight: $K_2Cr_2O_7$; 294.

Characteristics: Orange red crystals.

Solubility: Fairly soluble in water at room temperature. Freely soluble in hot water.

POTASSIUM BROMIDE. Restrainer in developers, also in bleachers.

Formula and molecular weight: KBr; 119.

Characteristics: Colourless cubical crystals.

Solubility: Freely soluble in water at room temperature.

POTASSIUM CARBONATE. Alkali in developers.

Formula and molecular weight: K_2CO_3; 138.

Characteristics: Very hygroscopic white powder. Keeps in well stoppered bottles.

Solubility: Highly soluble in water at room temperature.

POTASSIUM CHLORIDE. Used in some bleachers and sensitizers.

Formula and molecular weight. KCl; 74·5.

Characteristics: White crystalline powder.

Solubility: Freely soluble in water at room temperature.

POTASSIUM CHLOROPLATINITE. Used in certain toners and intensifiers.

Formula and molecular weight: K_2PtCl_4; 415.

Characteristics: Red crystals.

Solubility: Very slightly soluble in water.

POTASSIUM CHROMATE. Used in certain toners.

Formula and molecular weight: K_2CrO_4; 194.

Characteristics: Yellow crystals.

Solubility: Highly soluble in water at room temperature.

POTASSIUM CHROMIUM SULPHATE. Full chemical name of hardening agent used in fixing baths. Also known as chrome alum by analogy with the chemically related ordinary alum.

See also: *Alum, chrome.*

POTASSIUM CITRATE. Used in many toners.

Formula and molecular weight: $K_3C_6H_5O_7.H_2O$; 324.

Characteristics: White crystals.

Solubility: Highly soluble in water.

POTASSIUM CYANIDE. Used in reducers and solvents for silver.

Formula and molecular weight: KCN; 65

Characteristics: White lumps. Very poisonous. Must be kept in stoppered bottles to prevent deterioration.

Solubility: Highly soluble in water. Solutions smell of bitter almonds.

POTASSIUM DICHROMATE. Sensitizer used in carbro, gum bichromate and other processes.

See also: *Potassium bichromate.*

POTASSIUM FERRICYANIDE. Red prussiate of potash. Used in Farmer's reducer and some bleachers and toners.

Formula and molecular weight: $K_3Fe(CN)_6$; 329.

CC-0. Agrihouse. Digital Presevation Foundation. Chennai

Characteristics: Red crystals, giving an intensely yellow solution. Poisonous.
Solubility: Freely soluble in water at room temperature.

POTASSIUM HYDROXIDE. Caustic potash; potassium hydrate. Strong alkali in high energy developers.
Formula and molecular weight: KOH; 56.
Characteristics: White hygroscopic sticks or pellets. Both the solid and the solution are corrosive.
Solubility: Highly soluble in water at room temperature.

POTASSIUM IODIDE. Used in certain bleachers, reducers and intensifiers.
Formula and molecular weight: KI; 166.
Characteristics: White crystals.
Solubility: Highly soluble in water at room temperature.

POTASSIUM METABISULPHITE. Acidifying agent in acid fixers and stop baths, preservative in developers.
Formula and molecular weight: $K_2S_2O_5$; 222.
Characteristics: White crystals.
Solubility: Freely soluble in water at room temperature.

POTASSIUM OXALATE. Used in certain toners.
Formula and molecular weight: $K_2(CO_2)_2.H_2O$; 184.
Characteristics: White crystals. Poisonous.
Solubility: Freely soluble in water at room temperature.

POTASSIUM PERMANGANATE. Used in reducers, bleachers, stain removers.
Formula and molecular weight: $KMnO_4$; 158.
Characteristics: Violet-black crystals, giving an intensely purple solution.
Solubility: Fairly soluble in water at room temperature.

POTASSIUM PERSULPHATE. Used instead of ammonium persulphate in reducers.
Formula and molecular weight: $K_2S_2O_8$; 270.
Characteristics: White powder.
Solubility: Slightly soluble in water at room temperature.

POTASSIUM PYROSULPHITE. Obsolete name for potassium metabisulphite, used as an acidifying agent in stop baths, hardeners, and fixers, and also as a preservative in certain developers.

POTASSIUM QUADROXALATE. Potassium tetroxalate. Used in certain toners.
Formula and molecular weight: $KH(CO_2)_2.H_2(CO_2)_2.2H_2O$; 254.
Characteristics: White powder. Poisonous.
Solubility: Fairly soluble in water.

POTASSIUM SULPHIDE. Liver of sulphur. Used in some sulphide toners.
Formula and molecular weight: K_2S; 110.
Characteristics: When pure, white very hygroscopic powder. The commercial liver of sulphur contains rather more sulphur than suggested by the chemical formula; it is a reddish substance.
Solubility: Highly soluble in water.

POTASSIUM SULPHOCYANIDE. Potassium thiocyanate; potassium rhodanate. Addition to fine grain developers, also may replace ammonium sulphocyanide in gold toners.
Formula and molecular weight: KCNS; 97.
Characteristics: White hygroscopic crystals. Keep in stoppered bottles.
Solubility: Highly soluble in water at room temperature.

POTASSIUM TETROXALATE. Constituent of certain toning baths. It is a white powder which is poisonous.
See also: *Potassium quadroxalate.*

POTASSIUM THIOCYANATE. Chemical used in fine grain developers and sometimes in gold toners.
See also: *Potassium sulphocyanide.*

POUNCY, JOHN, *c.* 1820–94. English professional photographer at Dorchester. The first to produce carbon prints (in gum) from photographic negatives, *c.* 1857, which were, however, criticized for lack of half-tone. Published *Dorsetshire Photographically Illustrated* (1857)—the first British book illustrated by photo-lithography, by his own technique. The stones were retouched to some extent.

PRESERVATIVE. Chemical included in a developer mainly to protect the developing agent in the solution from premature oxidation.
Sodium Sulphite. The most common preservative is sodium sulphite. This is available in two forms: powder (anhydrous) and crystals. The two are interchangeable in all formulae; one part (by weight) of anhydrous sodium sulphite is exactly equivalent to two parts of the crystalline salt. The other part is merely water combined in the crystals.

The advantages of using anhydrous sodium sulphite are: it dissolves more quickly and easily, and it is cheaper than the equivalent amount of crystals.

The disadvantage of the anhydrous salt is that any deterioration can only be determined by chemical analysis. Sodium sulphite slowly

changes into sodium sulphate which looks much the same as sodium sulphate powder. But on sodium sulphite crystals the sulphate forms a white deposit which can be seen at once. If this deposit is serious, the crystals should be quickly rinsed in cold water and dried before they are weighed out.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The amount of sodium sulphite used in a formula varies with the type of developer.

Normal negative and positive developers contain about 1–4 per cent sodium sulphite in the working solution.

Pyro-metol developers and also special tanning formulae may contain as little as 0·05 per cent, or in some cases none at all.

On the other hand, many concentrated fine-grain developers contain as much as 10 per cent sodium sulphite.

Other Preservatives. The only other preservatives of any importance are the bisulphites and metabisulphites of sodium and potassium. They are freely interchangeable with each other, but not always with sodium sulphite. The chemically equivalent amounts are as below.

EQUIVALENTS OF BISULPHITES

Potassium Metabisulphite	*Sodium Metabisulphite*	*Sodium Bisulphite*	*Sodium Sulphite (anhyd)*
100 parts	86 parts	94 parts	114 parts
117 parts	100 parts	110 parts	133 parts
106 parts	91 parts	100 parts	121 parts
88 parts	76 parts	83 parts	100 parts

For most practical purposes the difference between the bisulphites and metabisulphites can be ignored. The maximum error of about 15 per cent is too small to matter.

The main difference between sodium sulphite and the bisulphites is that the bisulphites are acid in solution, while the sulphite is weakly alkaline. Bisulphites are particularly useful as preservatives in concentrated developers made up in two solutions, e.g., pyro developers. One solution contains only developing agent and preservative, while the alkali is kept separately as the other solution until required for use.

As most developing agents will keep much better in acid solution, considerably less bisulphite is needed than the equivalent amount of sodium sulphite. The chemical equivalent of the bisulphites is less than for sodium sulphite; the practical equivalents are less still. As the acid bisulphites reduce the alkalinity of the developer, the formula must contain enough excess alkali. L.A.M.

PRESS CAMERA

While press photographers nowadays may use several advanced cameras such as precision miniatures, twin lens and single lens reflex models, etc., there is a traditional camera type specifically associated with press work. This is derived from a medium-size folding plate camera, and notable features are instant readiness for action, higher shutter speeds, and a considerable degree of versatility to cope with any type of subject.

Negative Material. Press cameras mostly use plates or sheet film (nowadays generally the latter) in suitable holders. The usual sizes are from $2\frac{1}{2} \times 3\frac{1}{2}$ ins. (6 × 9 cm.) to 4 × 5 ins. (10 × 12·5 cm.). The 9 × 12 cm. ($3\frac{1}{2} \times 4\frac{3}{4}$ ins.) size is particularly popular on the Continent.

The plates or films are mostly carried in double holders to permit quick changing over from one shot to a second one. The exposures are processed individually—almost a "must" for press photography.

If required, roll film holders can be fitted to several press cameras for use of roll film material. Film packs (in adapters) can also be used as an alternative to plates or sheet film.

A number of press cameras take special magazines for roll film or perforated 70 mm. film. The latter type of magazine holds up to 50 exposures and frequently carries a rapid film transport lever for quick sequence shooting.

Body Construction. The body is usually collapsible, the lens unit being joined to the back by bellows. The standard lens may move on runners on a folding baseboard or alternatively it may be mounted on an extending lazy-tongs system. In either case, positive stops permit rapid opening of the camera. Often several such stops are provided to cater for the different extensions necessary with interchangeable lenses of various focal lengths.

Press cameras with a folding baseboard may incorporate a limited range of camera movements to cope with unusual subjects requiring perspective correction.

A few cameras of this type have a rigid body; this makes for quicker operation but limits the use of interchangeable lenses, as well as the focusing range.

On a number of models the back carrying the film holder rotates through 90° or 360° to permit upright or horizontal shots without changing the grip on the camera.

The film holders slide into retaining grooves in the back, being interchangeable against a ground glass screen. On quite a few modern models the ground glass screen remains permanently in position, being held by spring-loaded arms. The film holder then simply slides underneath the screen, pushing the latter back, for the exposure. This makes insertion and removal of the film holders a specially rapid operation.

A leather strap and sometimes a special handle, provides a steady grip on the camera.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PROFESSIONAL PRESS CAMERA. Although 35 mm. miniature and roll film reflex cameras are widely used for press work, the larger size press camera is still popular among newspaper photographers. This is due to its versatility in the use of different types of material such as sheet film, plates as well as roll film and perforated 70 mm. film in special adaptor backs. Top left: Side view of bellows type press camera with focal plane and diaphragm shutters. Top right: Front view of bellows camera. Bottom left: Front view of rigid press camera. Bottom right: Side view of rigid press camera with roll film back.

A, rangefinder eyepiece. B, winding knob for focal plane shutter. C, focal plane shutter speeds setting. D, coupled rangefinder. E, flash socket. F, spring-loaded ground glass screen for rapid insertion of film holders. G, body release. H, rising front and tilt controls. J, double extension runners on baseboard. K, focusing knob. Q, film transport crank for use with roll film back. R, frame finder. S, interchangeable lens panel. T, release linkage. U, carriage lock. V, roll film back. W, back release.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

An important point is that all exposed metal parts must be corrosion proof, since press cameras are often used in all kinds of adverse weather.

Focusing. Professional press photographers habitually estimate the distance of the subject, and focus the lens by scale. In experienced hands this is the quickest method.

The focusing movement is usually a rack and pinion drive, controlled by a handy knob on one or both sides of the camera. The focusing scale may be mounted on the baseboard; some modern models carry it on the body so that it is easily visible from the shooting position.

The folding baseboard type of press camera usually provides double bellows extension for close-ups and macrophotography with the standard or wide angle lens.

In common with nearly all plate cameras, press models carry a ground glass rear focusing screen for accurate focusing. This is not, however, used in normal press work, since that method of focusing is much too slow for most purposes.

A number of press cameras carry a coupled or uncoupled rangefinder mounted on, or built into, the body. This is useful in sport and action work. In a few cases the rangefinder incorporates a small torch bulb powered by a battery; this can be made to project a light beam through each rangefinder window. When the beams meet in the subject plane, the convergence is the same as for rays of light from the subject to the rangefinder. That therefore indicates that the rangefinder is set to the correct distance and provides a useful focusing aid when the light is too poor for more orthodox focusing.

Viewfinders. The standard finder for most press cameras is the traditional full-size wire frame. It indicates the field limits reasonably accurately (some cameras provide a parallax adjustment) and allows the photographer to follow rapid movement in sports and similar subjects with certainty.

Where the front frame of the finder is fixed on the lens panel, the finder automatically compensates for the change in angle of view (not parallax) at close subject distances, and also indicates the correct field area with wide angle and long focus lenses. This is because the lens panel has to be rocked back or forward to a new infinity position, which obviously brings the front frame nearer or farther away from the rear sight.

In addition, several press cameras employ accessory or built-in optical finders. On advanced camera models such finders may feature automatic parallax correction (by a mask movement coupled to the focusing mechanism), and an adjustable angle of view to cope with different lenses.

Lenses. Most press cameras take interchangeable lenses, changing over being effected by the use of removable lens panels. In a camera intended for a between-the-lens shutter each lens may be mounted in its own shutter. Alternatively, the lens may screw or clip into the front of a fixed shutter.

Certain press models with coupled rangefinders extend this coupling to a wide angle and a long focus lens in addition to the standard one. Interchangeable cams adapt the rangefinder system to the lens movement. The cams may be individually ground to shape to allow for small variations in focal length, etc. This practice is common with high-precision cameras; the camera is once and for all set to a particular lens outfit until a completely different series of cams is fitted.

Standard focal lengths range from 4 ins. (10 cm.) for the $2\frac{1}{2} \times 3\frac{1}{4}$ ins. models up to $6\frac{1}{2}$ ins. (16·3 cm.) for 4×5 ins. ($10 \times 12{\cdot}7$ cm.) negatives.

Shutters. Many press cameras carry a focal plane shutter; between-the-lens shutters seem to be less popular, but are far from absent.

The focal plane shutter can yield shorter effective exposures (to 1/1000 second) and makes lens changing easier. Between-the-lens shutters, though rarely exceeding 1/500 second as top speed, are more convenient to synchronize with all types of flash bulbs and electronic flash at all shutter speeds. The use of separate shutters for each lens does, however, increase the cost of alternative lenses.

To utilize the advantages of each type, some press cameras carry both a focal plane and a between-the-lens shutter. The release may be coupled so as to trip either shutter at will. Naturally, the between-the-lens shutter must be set open (on "Time") for exposures with the focal plane unit, and vice versa. Focal plane shutter units are also available as accessory attachments for specific models. L.A.M.

PRESS PHOTOGRAPHY. The function of news photography is to keep the public informed about everyday events, and personalities connected with them, throughout the world. In many newspapers and periodicals photographic illustrations occupy as much space as the text. The press photographer must be able to cope with any situation, nearly always using a hand camera of the press or miniature type. On some occasions he may be expected to supply the accompanying news story.

Sources. News photographs fall into three categories—those taken by newspaper and periodical photographers, those taken by big agencies which have representatives in every quarter of the globe, and (in most countries) those taken by small agencies, free-lances, and amateurs.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Of these the main supply of news photographs of international and general interest comes from the big agencies. They employ a number of photographers, some of whom, like many newspaper correspondents, live in the countries in which they operate; others are continually moving from place to place. Together, these photographers cover every happening of outstanding interest. The more important of their pictures are as a rule sent to the capitals of the world by radio or by wire; they are then "piped" or retransmitted simultaneously to newspaper and agency offices in other cities and towns. This system is very highly developed in the United States. Photographs not of the first importance are sent by air freight or air mail.

Newspapers employ much the same methods, but their operations are usually limited to places where important stories have broken. Today the newspapers tend to employ their own photographers on events comparatively near home, and to rely on the big agencies for international news. The difficulty and expense of complete coverage are so great that no individual newspaper can compete with the agencies in this field. The mass of photographs produced by the small agency, the freelance and the amateur help to fill a considerable amount of space in publications of all kinds. But the pictures from domestic sources, in whatever country they are taken, are usually of no more than local interest. Only amateurs who have the good fortune to be engaged in foreign expeditions, or to be present on some important occasion, or who have similar special opportunities, can hope to secure photographs of any real news value.

Publication of the news photographs from these various sources is shared by the daily and Sunday papers and periodicals. It is probable that the periodical press now devotes more space to illustrations than do the newspapers. The requirements differ: newspapers will give one or two pictures to a subject, but a periodical will frequently spread a subject over several pages, perhaps using as many as twenty pictures.

Equipment. This variation in presentation of a story may call for more than one type of equipment. In general, the larger press camera is more popular for daily newspaper work and the smaller sizes for series or sets of photographs for periodical publications. 4 × 5 ins. and 9 × 12 cm. press cameras are still very popular with newspaper and agency photographers. They are usually loaded with panchromatic plates or cut film, and are fitted with flash bulb or electronic flash equipment (which gives a much faster speed). When series of photographs are in demand for periodical work, 35 mm. or roll film cameras are more suitable. Colour news photography is well established for periodical publications and some Sunday newspapers in the United States.

News subjects cover such a great range that both newspapers and agencies must be equipped with a wide variety of apparatus from copying cameras to special telephoto cameras equipped with lenses up to 60 ins. focal length. Television wire and radio receiving instruments and portable transmitters are also in general use in the bigger offices. The latter instruments are usually operated by trained telegraphists who work in the newspaper or agency offices and accompany the photographers on their assignments. Satisfactory reproductions are made even though the picture may be broken both by the television signal and by the half-tone screen. Many newspapers are equipped to receive pictures by wire from the leading agencies. Often, agencies and newspapers have studios in which fashion and other subjects are photographed for editorial features.

Speed is necessarily the main controlling factor in the production of newspaper illustrations, and though the results of wire and radio transmissions can be excellent, pictures often have to be rushed to such an extent that quality is lost.

Reproduction. Glossy bromide papers are used for newspaper half-tone reproduction. The printer aims at turning out reasonably strong well-balanced prints to reduce time spent in retouching. Even so, all newspaper process departments employ artist retouchers to emphasize or tone down parts of the picture as required by the blockmaker. Retouching is necessary because of the loss caused by the use of relatively coarse half-tone screens of sixty to seventy lines to the inch (which produce the dot formation in the reproduction) and by hurried printing on poor paper. This does not apply in the same degree to periodical printing. Here some retouching is necessary, but the finer screens used and better quality paper ensure a more faithful reproduction of the original photograph. In photogravure printing the retouching is usually done on the positives after the original photographs have been copied. But whatever the process, the better the original print the better the result.

The electronic "block-making" process, in which the printing surface is cut in plastic, or metal, calls for a strong print. In principle this process is similar to that employed for transmitting photographs by wire or radio. The various tones of the picture are scanned by a beam of light transmitted through a photoelectric cell, which operates a stylus. The stylus cuts or burns the plastic or metal and builds up a pattern of dots similar to that formed by the half-tone screen.

Restrictions and Censorship. Freedom to photograph varies in different countries. In Great Britain photography is not allowed in any court of law, or in the Houses of Parliament when they are sitting.

Press photography is restricted at functions

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

when royalty is present, or wherever lack of space prevents more than a limited number of photographers from working together at the same time. To ensure fairness of representation a rota system of permits, in which newspapers and agencies share, is in operation in Great Britain. In London the system is administered by the Newspaper Proprietors Association, whose secretary, with the advice of representatives of the various concerns interested, allocates permits in rotation from the list of applicants. On the very few occasions when only one photographer is allowed, the pictures are pooled and made available to all publications.

Press photographers have in general a great deal of freedom. In London the majority hold a Press card, carrying a portrait of the photographer, issued by Scotland Yard. In the United States press photographers are still less restricted, and photography is permitted even in courts of law, the Senate, and the House of Representatives. The press photographer is allowed considerable freedom in the countries of Western Europe, though special permits are necessary for important indoor functions. In Great Britain there is little in the way of censorship in peacetime; the exceptions are new aircraft, new weapons, and new naval equipment, but these are rarely visible to the press.

Sometimes during naval exercises the Admiralty ask that all pictures taken by the press shall be submitted to be passed by the Naval Censor, but it is unusual for a photograph to be stopped.

Other photographs which may be classed in the category of news are those supplied to the press generally by the press or public relations' officers of business firms, the big industries, film companies, the entertainment world, transport companies, travel agents, and other bodies. These sources usually offer the pictures of their activities for reproduction without fee in return for the publicity. U.V.B.

PRETSCH, PAUL. 1808–73. Austrian inventor of photogalvanography, 1854, a photo-electro-engraving process, and manager of the Imperial Printing Establishment in Vienna. Pretsch resided in England for nine years in order to exploit his invention, and started publishing *Photographic Art Treasures*, November 1856—the first publication of photographs in printing-ink, i.e., photo-engraving. Talbot incorrectly alleged that photogalvanography infringed his own photo-engraving patent and, owing to his constant interference, Pretsch's firm failed and he returned to Vienna.

PRICE, WILLIAM LAKE, *c.* 1810–96. English watercolour painter, photographer from 1854. One of the earliest photographers in Britain to compose historical and literary subjects, and to make combination pictures from several negatives (1855). He gave up photography after eight years' activity, during which he specialized in reproductions of paintings. His handbook (1858) was the first to stress the aesthetic aspect of photography.

PRICES OF COMMERCIAL PHOTOGRAPHS. Shrewd and careful pricing of photographic work is essential to the success of a commercial, industrial or portrait studio. The real danger is in fixing charges too low through not making a proper assessment of the costs involved. But the making of photographs is largely a manufacturing process and is subject to detailed costing like any other industry.

Costs can be divided under two headings:

(1) Photographic materials—plates and films, chemicals, printing papers, mounts, mounting tissue, frames, colouring.

(2) Non-photographic expenses—proprietor's salary, staff wages, rent and rates, insurances, services (gas, electricity, water, telephone), depreciation of equipment and repairs, advertising, stationery, packing and postage, professional fees, transport, trade expenses, bank charges.

The percentage of the turnover to be allocated to each of these items varies considerably with the type of business, commercial or portraiture.

Commercial Photography. A large percentage of the over-all expenses is taken up by such items as models' fees, extensive fabricated scenery, travelling, and the transport of heavy equipment. Time is also a big factor; not only the actual time spent operating the camera, but also waiting time. In some industries this is so great that the photographer may find it best to charge a daily rate for his services irrespective of how many photographs are taken; this is preferable to trying to assess charges on a cost per photograph basis.

COMMERCIAL PHOTOGRAPHY CHARGES

Service	*Charge* £	s.	d.
Photographing			
Attending premises within a radius of five miles, taking one photograph and supplying one finished print in black and white ... ... from	3	3	0
Subsequent views up to five taken on same visit, with one finished print of each	2	2	0
Subsequent views after the first five with one finished print of each	1	15	0
Supplying additional prints and slides			
$4\frac{3}{4} \times 6\frac{1}{2}$ ins. or smaller		7	0
$6\frac{1}{2} \times 8\frac{1}{2}$ ins.		8	0
8 × 10 ins.		10	0
10 × 12 ins.		13	0
12 × 15 ins.		17	0
16 × 20 ins.	1	10	0
Over 16 × 20 ins., per square foot		15	0
2 × 2 ins. or $3\frac{1}{4} \times 3\frac{1}{4}$ ins. slides		10	0

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

In addition to these, the photographer may make the following extra charges:

(1) Models' fees at cost, plus a percentage to cover overheads.

(2) Substantial fee for use of photograph for a poster.

(3) Fee to cover hiring charge of properties, or use of properties if belonging to photographer, plus percentage to cover overheads.

(4) Charge for operator's travelling time on outdoor work beyond a five mile radius of studio, plus 100 per cent to allow for unproductive time.

(5) Operator's hotel and travelling expenses at cost.

(6) Charge for delays caused by customer and not expected at time order accepted, on basis of time lost plus 100 per cent.

Further points are that in cases where additional expense has been incurred owing to work having to be done at abnormal times, a higher rate should be charged to recover the extra costs. Also an original negative should not be lent, but a copy negative made for this purpose, invoiced as for total surrender and credited on its return less any charge which may be agreed. And if prints of stock negatives are supplied to publishers, advertising agencies, art studios, printers, etc., for possible selection, these should be invoiced out and credited on return.

Colour Photographs. Professional photographers who supply colour photographs, either as transparencies or prints, for advertising and reproduction, etc., are under no illusion as to the technical problems encountered arising from the client requiring faithful colour rendering of his subject and from the lack of latitude and other properties peculiar only to colour materials.

As a result of these restrictions and the comparatively high cost of materials, charges for all forms of colour photography should be considerably higher than for black-and-white work. Charges for creative and scientifically accurate colour photography, and with models, should be correspondingly higher, especially to allow for the extra darkroom work involved and it is impossible to lay down specific recommendations for work in these highly specialized fields.

Portraiture. Compared to the commercial photographer, the portrait photographer concentrating on studio work spends relatively little on advertising, travelling, wages and postage, and has an easier task in assessing costs and prices.

Prevailing charges are by no means as stable over the country as those for commercial work and variations can be observed depending on the type of district in which the studio is situated.

The following examples give some idea of the charges made:

(1) A seaside town in Essex, two towns on the south coast and a large town in the south-west: sitting fee, one guinea, and four proofs supplied, 10s. 6d. single figures, 15s. groups. Portraits, from 5s. for 3 × 4 ins. to £1. 1s. for 8 × 10 ins.

(2) London, two seaside towns on the south coast, a small town in the south-east, a small seaside town in the south-west and a large town in the Midlands: minimum charge payable at the time of the sitting—3 guineas including sitting, submission of proofs and one finished portrait any size up to 9 × 11 ins., or one 6 × 8 ins., or three 6 × 8 ins., or two 4 × 6 ins.

(3) London outskirts, a fairly large seaside town in the west, a small provincial town in the south-west and a south-west port: minimum charge payable at the time of the sitting—2 guineas including sitting, submission of proofs and three 6 × 8 ins. finished portraits, or four 4 × 6 ins.

(4) A seaside town in the south-west, a town in Kent and Northern Ireland: sitting and one 6 × 8 ins. print, 1 guinea; three copies 2½ guineas. Sitting and one 4 × 6 ins. print, 15s.; three copies 2 guineas. Deposit payable at time of sitting and afterwards deducted from order.

I.I.P. Publications. For further assistance the photographer is referred to the Institute of Incorporated Photographers which can supply information on the methods of charging as follows:

(1) Interior or exterior work away from the studio (monochrome).

(2) Work in studio (monochrome).

(3) Colour photography.

The following publications are available from the I.I.P.: *Conditions of Engagement and Scale of Professional Fees for Commercial and Industrial Photography; Fees and Conditions of Granting Reproduction Rights in Copyright Photographs.*

Prices in the U.S.A. Costing and determination of prices run along simil arlines to British practice, though the expenses, wages, and salaries are of course different.

Typical figures for an average small commercial job are $25 to $35 with one 8 × 10 ins. print; additional prints being charged at $1 each. Portraits run from $25 with one 8 × 10 ins. print, with additional prints from $2.50 each. Average colour jobs cost around $100, and additional 8 × 10 ins. prints from $10 each. J.Bl.

See also: *Costing; Reproduction fees; Selling photographs.*

Book: *Business of Photography*, by C. Abel (London).

PRIMARY COLOURS. Three main colour bands each covering about one-third of the visible spectrum (blue, green, and red) which on additive mixing will produce white. Theoretically, any colour can be obtained by suitable combination of light of the three primary colours only.

See also: *Colour synthesis.*

CC-0. Alexandria Digital Preservation Foundation Inc.

PRIMULINE PROCESS. Alternative name for the diazotype process, by which an image could be printed on to a variety of supports (e.g., fabrics, paper).

PRIMULINE YELLOW. Bright yellow aniline dye used in diazotype printing. It is used in preparing the sensitized support.

See also: *Fabric printing, Printing processes (obsolete).*

PRINCIPAL AXIS. Straight line about which a lens is symmetrical—i.e., the line passing through the centres of curvature of all the lens elements, and normal to all plane surfaces.

PRINCIPAL LIGHT. Source of subject lighting which creates the dominating highlights and shadows on the subject. This is the light that gives the basic impression of relief, or roundness, to the subject. If there is no principal light the subject is apt to appear flat and lacking in three-dimensional form.

In daylight, the principal light is, of course, the sun.

This is the most usual and natural form of lighting, so when an orthodox photograph is taken with artificial lighting it is usual to place the principal light more or less above the subject to produce the same effect.

See also: *Lighting the subject.*

PRINCIPAL PLANES. Term in optics referring to planes passing through the nodal points of a lens at right angles to its optical axis.

PRINT. In photography, a positive image created on a prepared surface—generally paper—by the agency of a photographic negative.

More than one print can be produced in this way from the same negative, and the positive image may be created by photographic means or it may involve a variety of physical or chemical effects.

See also: *Printing materials.*

PRINTED CIRCUIT. Electric wiring layout usually produced photographically by exposing a negative of the drawn circuit on to a thin copper layer, laminated to an insulating carrier and coated with a sensitized colloid layer. After exposure and hot water treatment the latter forms a resist to protect the areas required for the wiring, while the rest of the copper surface is etched away. After removal of the resist there remains the wiring layout on the laminated surface.

Producing circuits in this way is considerably faster and quicker than the classical method of wiring up small resistors, capacitors, etc. Also, such printed circuits can be made extremely small for specialized applications.

See also: *Photo-etching.*

PRINT FINISHING. Term for all the various non-photographic operations carried out on the print after it has been processed and washed. The finishing operations are intended to improve the appearance of the print and present it in a form which makes the most of its qualities.

The methods in common use are:

(1) Spotting with opaque pigment or dye to obliterate white spots or scratches due to dust, air bubbles, etc.

(2) Knifing away black spots to convert them into white marks which can then be spotted out.

(3) Retouching with artists' brushes or with an airbrush to emphasize or subdue outlines or whole areas of tone.

(4) Building up density by handwork with either oil pigment or graphite powder.

(5) Colouring by hand with oil pigments, water colours or coloured dyes.

(6) Doping or waxing to subdue broken reflections from the surface of the paper and so deepen the dark tones of the picture.

(7) Glazing by which a paper with a glossy surface is given a still higher glaze by squeegeeing it while wet into contact with a highly polished glass or metal surface.

(8) Trimming the edges of the print to remove distracting detail and give better balance to the composition.

(9) Mounting the print on a support to give it importance and to protect its edges from injury.

(10) Framing to isolate the photograph from its surroundings and prevent the attention of the observer from straying away. F.P.

Book: *Retouching*, by O. R. Croy (London).

PRINTING. Process by which an image is made by exposing sensitized material to light passing through a negative or positive transparency. This exposure is made either with the negative in contact with the sensitized material (contact printing) or by projecting an image of the negative on to the material (projection printing). Because it is usually intended to give an enlarged image, projection printing is more commonly known as enlarging.

Printing is mostly done by artificial light, but when daylight is used (as occasionally for contact printing) the process is commonly called "daylight printing".

PRINTING BOX. Improved type of printing frame. A box contains the printing light, and the negative and paper are held down on to a glass window in the top. The exposure is controlled by switching the light in the box on and off.

See also: *Contact printer.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PRINTING FRAME. Wood, metal or plastic frame in which a piece of sensitized paper is exposed behind a negative to produce a photographic positive print.

See also: *Contact printers.*

PRINTING IN. Selective exposure which is sometimes given, in enlarging, to certain parts of a print. This local increase in exposure is used to bring out detail or increase density in areas of the print that would otherwise appear too light.

The method is to use a sheet of metal or opaque card having a hole of the required shape cut in it. The main exposure for the print is given, and then the mask is held above the printing paper so as further to expose the required area through the hole. The mask is kept in constant motion so that the additional density will blend with the surrounding parts.

To print in large areas, such as a sky, a plain card is used to shade the remainder of the image; its edge may be straight, or cut or roughly torn to the required outline.

Some photographers are skilled in shading with the hands, arranging them to throw the required shadow outline or spot of light.

The term is also used to describe methods of improving a photograph by supplementary exposures through other negatives at the printing stage—e.g., adding clouds to fill in an otherwise blank sky.

See also: *Cloud negatives; Combination printing; Flashing; Shading and spot printing.*

PRINTING MATERIALS. There are two principal types of material used for making positive prints from a negative: printing-out emulsions and development emulsions.

Printing-out Emulsions. These usually are coated on a paper base. When they are exposed to daylight behind a negative they gradually form a visible image. When the image has printed out sufficiently, the unused salts are removed by fixing, leaving a permanent print.

Printing-out papers are suitable for contact printing by daylight only.

Development Emulsions. These may be coated on paper for making prints, or on glass to make lantern plates, or positive film for making transparencies. When these materials are exposed behind a negative they form a latent image which must be developed.

Development materials are almost always printed by exposure to artificial light. The slow development papers and transparency materials are used for contact printing, while the faster types are used for printing by projection in an enlarger.

Mostly contact printing and enlarging papers are blue-sensitive only. Mixtures of blue-sensitive and orthochromatic emulsions of different gradations are used in variable contrast papers, and printed through different filters according to the required print contrast. Panchromatic papers are used for making black-and-white prints from colour negatives.

Rapid processing document printing papers and films may incorporate a developing agent in the silver halide emulsion; such papers are suitable for rapid machine processing with roller type processors.

TYPES OF PRINTING MATERIAL

Type	*Characteristics*	*Uses*
Papers		
Chloride	Slow silver chloride emulsion; in up to 6 contrast grades	Contact printing of normal negatives
Slow chlorobromide	Predominantly silver chloride emulsion with silver bromide; in 1 or 2 contrast grades	Warm-tone contact prints or enlargements
Fast chlorobromide	Predominantly silver bromide emulsion with silver chloride; in 3–4 contrast grades and wide range of surfaces	Warm-tone enlargements of ordinary negatives
Bromide	Fast silver bromide emulsion; in up to 5 contrast grades and wide range of surfaces	General enlarging work
Waterproof bromide	Bromide paper coated on lacquered paper base which is practically waterproof	High-speed printing, also where dimensional stability is important
Variable contrast	Two bromide emulsions of different colour sensitivity and contrast either mixed or coated on top of each other; contrast of image controlled by varying colour of printing light.	General enlarging work, especially when it is inconvenient to keep several paper grades in stock
Panchromatic bromide	Fully colour sensitized enlarging paper	Black-and-white enlargements from colour negatives
Document	Chloride or bromide emulsions, sometimes orthochromatic, of extreme contrast; may be on extra thin paper	Direct document copying or printing line negatives
Reflex	Chloride emulsion of extreme contrast, for reflex printing processes	Reflex printing of documents and line originals
Rapid processing	Chloride and bromide emulsions of various speeds (especially document papers) incorporating developing agents	Document copying, but also normal prints and enlargements, intended for high speed processing
Direct reversal	Extremely slow prefogged emulsion designed for direct reversal	Making positive prints from positive images
P.O.P. (printing-out paper)	Silver chloride emulsion containing free silver nitrate, producing an image by printing out without development	Contact printing of normal negatives by daylight

TYPES OF PRINTING MATERIAL (*continued*)

Type	Characteristics	Use
Films		
Positive film	Sheet or 35 mm. miniature film with silver bromide emulsion (sheet film similar to blue-sensitive negative film)	Making positive transparencies and film strips
Contact film	Extremely slow silver chloride emulsion of very high contrast	Contact printing of document and line negatives
Document miniature	35 mm. miniature film with extra-fine grain high contrast emulsion	Printing microfilm negatives
Rapid processing	Chloride and bromide emulsions of high control incorporating developing agents	Making transparent document copies (for use as dyeline masters) by rapid processing systems
Plates		
Chloride lantern	Silver chloride emulsion	Making slides by contact printing only
Warm tone lantern	Silver chloride and bromide emulsion	Making slides by contact or projection, to yield warm-tone images by direct development
Bromide lantern	Silver bromide emulsion	Making slides by contact or projection to yield black tones (blue-sensitive, slow, negative emulsions are sometimes used for same purpose)

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Other Materials. Special materials are also manufactured for some modern printing processes. These include matrix film, for making dye transfer colour prints, integral tripack colour printing materials, and stripping emulsions used in certain monochrome and colour processes.

In addition to the commercially available printing materials, there are also numerous formulae for the sensitizing of various supports for printing. Most of these are intended for daylight printing, although it is possible to prepare an emulsion sufficiently sensitive for printing by artificial light. The majority of these formulae originated as early printing processes, but a few still survive for fabric printing, document photography, etc. L.A.M.

See also: *Cine film; Colour materials; Document photography; Fabric printing; Obsolete printing processes; Papers; Printing on special supports; Reversal materials; Slide (transparency); Stripping; Transfer coating; Transparency materials.*

PRINTING ON SPECIAL SUPPORTS. There are four ways of printing photographic images on special supports:

(1) Daylight printing, using sensitive silver salts or dye intermediates. This is mainly suitable for fabrics, but it can also be used for printing on other supports, including metal surfaces. The negative must be the same size as the image required, so it may be necessary to make enlarged negatives for large pictures.

(2) Daylight printing, using bichromated colloids, like gum or gelatin. These methods are mainly suitable for hard, non-porous surfaces like glass, glazed porcelain and enamel. They can also be used on specially prepared metal or even wooden surfaces.

(3) Artificial light printing, using silver salts or emulsions. Under certain circumstances this is suitable for fabrics as well as specially prepared solid surfaces. Such materials can usually be printed by contact or projection, and require development.

(4) Transfer printing methods. These also use silver salt emulsions which are exposed by contact or projection, and have to be developed. They are suitable for almost any prepared hard surface.

The best method for any particular case depends on the nature of the support. Most of the processes can be used equally well for making paper prints.

A number of sensitized fabrics, metals and other special materials are available commercially.

Solid Supports. Photographic images may be printed on to flat surfaces of wood, metal, glass and glazed articles by either daylight or artificial light.

The surface must first of all be prepared to prevent either absorption of the sensitized coating or subsequent chemical action on the image.

Glass and non-porous and chemically-neutral supports like glazed porcelain, china, and enamel, can be coated without further preparation, apart from cleaning the surface.

Wood may be painted with white cellulose enamel, or coated with a 10 per cent gelatin solution containing enough white zinc oxide to hide the grain. Any other surfaces of the wood support that are likely to get wet during processing are waterproofed with wax or varnish.

Metals may be protected by varnishing all the surfaces liable to come into contact with the processing solutions.

Large Supports. Printing and processing have to be modified if the support is part of an object too large for handling in a printing frame or processing dish. In such cases it is generally possible to improvise some form of clamp to keep the negative and sensitized surface in close contact under a sheet of plate-glass during exposure.

Large sensitized surfaces have to be swabbed or brushed over with the various processing solutions. Such surfaces can be most conveniently washed and rinsed by playing a spray or jet of water gently on them.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Daylight Printing. The surface after preparation is brushed over with a 10 per cent solution of potassium bromide, allowed to dry, and then brushed over with a 10 per cent solution of silver nitrate. The final coating must be applied in the darkroom by the light of a bromide paper type of safelight.

The sensitized surface is printed out by daylight behind the negative. Printing is continued until a faint image is visible. This is not the final image; the final image is developed in a 0·1 per cent solution of metol containing 2 per cent glacial acetic acid.

Processing. If the article is too bulky to be immersed in a developing dish, it may be developed by swabbing it over with cotton wool soaked in the developer.

As soon as the image is dense enough, it is washed over with clean water and immersed in or swabbed over with a 10 per cent sodium thiosulphate solution to fix it. A final washing for about thirty minutes completes the process.

Artificial Light Printing. Sensitized silver-halide gelatin emulsions are available for coating on to solid surfaces to be printed photographically. Such emulsions are usually supplied in the form of a powder which is mixed with warm water to give an emulsion thin enough to be sprayed on the prepared surface.

Small objects are coated by whirling as in the wet collodion process, but larger surfaces are coated by spraying. The procedure calls for special equipment and is certainly beyond the scope of the ordinary photographer.

This is the method adopted for coating wall surfaces for printing photo murals *in situ* by projection.

Transfer coating is a much more practical method for the photographer who only needs to make such prints occasionally. This is also used for printing photographic templates on sheet metal to mark it out for machining.

An alternative method is to use the surface as the final support for a print made by the carbon or carbro process.

Fabric Printing. Fabrics like linen, canvas, silk, cotton, etc., can also be used as supports for a photographic image. Usually the fabric is prepared by sizing, followed by treatment in a halide solution and finally in a silver nitrate solution. Alternatively a ferric oxalate and silver nitrate mixture may be used for sensitization. It is then printed out by daylight, washed, and fixed like printing-out paper.

Alternatively, the image may be formed by dyes in the fabric itself, using a process like diazotype. Even a mordant image can be produced by the action of light (e.g., using a bichromate sensitized fabric) which will then take mordant dyes.

L.A.M.

Book: *The Complete Art of Printing and Enlarging*, by O. R. Croy (London).

PRINTING-OUT PAPER (P.O.P.). Sensitive paper which produces a visible image on direct exposure, without the need for development.

The use of printing-out papers derives from Johann Heinrich Schultze's observations in 1727 that silver chloride and other silver salts darken when exposed to light and from Sir John Herschel's discovery in 1819 that the resulting image can be made permanent or "fixed" by immersing in a solution of sodium thiosulphate. The effect of light is to decompose the silver chloride and liberate photolytic silver; the sodium thiosulphate serves to remove the unaffected residual silver chloride.

The use of gelatin or collodion as protective colloids for the silver chloride led to the production of the original print-out emulsions. The presence of excess silver ions was found to increase the efficiency of the print-out process, probably due to absorption of the chlorine liberated during light exposure.

Conventional print-out papers have a very long tonal range. The colour of the photolytic silver is usually reddish-purple, which changes to a yellowish-brown during fixation because the hypo exerts a slight solvent action on the very fine-grained silver image.

Partial transformation of the silver deposit to gold by gold toning prior to fixing strengthens the image and gives it a bluish-purple colour. Toning is effected by bathing the print in a dilute gold chloride-ammonium thiocyanate solution. It was later found feasible to incorporate gold-toning compounds during the manufacture of print-out emulsions, thus originating the so-called self-toning papers which required only fixation after printing.

In general terms the above papers are relatively insensitive and require lengthy exposure to sources rich in ultra-violet, such as sunlight, arc-lamps, mercury vapour lamps, etc. Accordingly, for most photographic purposes, printing-out papers have long since been superseded by the much faster developing-out papers, e.g. chloride, chloro-bromide or bromide types, in which the latent image is rendered visible by development.

Printing-out papers are still employed to some extent for portrait proofing. In recent years there has been a great revival of interest in special print-out papers with unusual properties. These are distinguished by very high sensitivity to ultra-violet light sources, e.g. mercury-quartz lamps. The resulting feeble print-out image is subsequently intensified by a second exposure to light of a longer wavelength such as fluorescent lighting, tungsten lighting or weak daylight. This is effected without appreciable darkening of the background which originally received no ultra-violet exposure. The intensification process can be accelerated by heating the paper during the secondary exposure.

This type of material is extensively used for high-speed galvanometer trace-recording, e.g.

for aircraft and rocket research and for any similar purpose where an immediate print-out is required. The saving of time over wet processing procedures is a great advantage. The combination of high basic sensitivity plus controlled intensification enables very high writing speeds to be recorded.

If required, the print-out image may be made still more stable by the use of so-called permanizing solutions. Alternatively a black image on a white background may be produced by processing in a solvent developer after ultraviolet exposure. H.P.

PRINTING PROCESSES (OBSOLETE). It would be more correct to describe obsolete printing processes as prototypes of the printing processes in common use today for they relied on the same blackening, bleaching or physical effect of light on certain compounds and used the same sensitizing agents as those required in modern practice; it is only the earlier ways of employing these which are obsolete.

The following are some of those processes which had a spell of popularity during the first fifty years of photography.

Calotype or Talbotype. A good quality letter paper was sponged over with, or floated on, solutions of silver iodide and potassium iodide. When partially dry the excess potassium iodide was removed by bathing in distilled water. Before use, the paper was sensitized in a solution of silver nitrate, acetic acid and gallic acid.

After printing (under a similarly prepared paper negative) in bright sunlight, the feeble image resulting was brought up to the required strength by an application of solution similar to the silver nitrate sensitizer. It produced a rich warm brown image.

Fluorotype. Paper was washed over with a solution containing 2 per cent potassium bromide and ¼ per cent sodium fluoride in distilled water. When dry, the paper was made sensitive to light by floating it for two minutes on a 15 per cent solution of silver nitrate. Fluorotype was very sensitive to light and the inventor claimed that an image of a brightly lit scene could be obtained on it in the camera by an exposure of only half a minute. But the image, however obtained, was feeble and had to be intensified by brushing it over with a weak solution of sulphate of iron. It was afterwards fixed with hypo and washed.

Cyanotype. Invented by Sir John Herschel in 1842, it is still in use and known as the ferro-prussiate or blue-print process. Used mostly for copying drawings, it gives a white image on blue ground but can be used for printing continuous tone negatives providing they have plenty of contrast. Suitable well-sized paper is brushed over with a sensitizer which in its simplest form may consist of a solution of potassium ferricyanide and ferric ammonium citrate. Paper so prepared is printed out to the required depth and then washed in several changes of water, the last being slightly acidified with hydrochloric acid.

Pellet Process. This is a variation of cyanotype giving a blue image on a white ground (negative from negative, or positive from positive). It was introduced by H. Pellet in 1878.

Three stock solutions are required: 20 per cent gum arabic, 50 per cent ferric ammonium citrate, and 50 per cent ferric chloride.

The paper is brushed over with:

Gum arabic solution	20 parts
Ferric ammonium citrate solution	8 parts
Ferric chloride solution	5 parts

After printing, the image, which is yellow in colour, is treated with a 20 per cent solution of potassium ferrocyanide which turns it blue.

Ferro-gallic and Ferro-tannic Papers. Introduced by A. Poitevin in 1861, the ferro-gallic process, like cyanotype, relied on the reduction of ferric salts by light. The image was however formed by the combination of the resultant ferrous salts with gallic or tannic acid, yielding a deep purple or brown insoluble organic compound.

A suitable sensitizer was:

Gum arabic	5 ounces	125 grams
Ferric chloride	5 ounces	125 grams
Ferric sulphate	4 ounces	100 grams
Tartaric acid	350 grains	20 grams
Potassium chloride	4 ounces	100 grams
Water to make	40 ounces	1,000 c.cm.

The sensitizer was applied to well-sized paper, and the latter partially printed out under a negative. The image was developed in a 5 per cent solution of gallic or tannic acid containing about 1½ per cent of potash alum, and a trace of hydrochloric acid.

Albumen Prints. Prior to 1850 prints had been made on salted paper (i.e., impregnated with sodium chloride) brushed over with a solution of silver nitrate but these had little vigour. They needed a base that would hold more silver and this need was met when Blanquart-Evrard of Lille suggested coating the paper with a thin film of albumen (egg white) before it was sensitized by floating on a bath of silver nitrate solution. The prints so obtained were toned with gold chloride and the process remained in almost universal use for the next thirty years. It was eventually superseded by printing-out papers using collodion or gelatin as a vehicle for the sensitive silver salts.

Argentotype. Originally invented by Herschel in 1842, this process produced a silver image by utilizing the action of light on ferric salts. Iron salts (principally ferric oxalate), combined with silver nitrate, were mixed with dextrin or starch, coated on to a paper base, and printed out by daylight. The action of light transformed the ferric salts into ferrous salts which, in a suitable solvent developer, liberated a precipitate of metallic silver from the silver nitrate to form the image.

Kallitype. In this process, introduced by W. J.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Nichol, the sensitizer was ferric oxalate, which was reduced by light to ferrous oxalate. When this was dissolved in the presence of silver nitrate (usually incorporated in the paper), the ferrous salt reduced the silver nitrate to metallic silver which formed the image.

In practice a tough cartridge or drawing paper was first sized with starch, then floated on or brushed over with the following (or a similar) sensitizing solution:

Ferric oxalate	4¼ ounces	112 grams
Potassium oxalate	500 grains	28 grams
Silver nitrate	500 grains	28 grams
Water to make	20 ounces	500 c.cm.

Printing was done by daylight and continued till only the shadows were visible. The prints developed in:

Borax	1 ounce	25 grams
Sodium potassium tartrate (Rochelle salt)	525 grains	30 grams
Water to make	20 ounces	500 c.cm.

The use of a ferric ammonium citrate sensitizer, followed by development in plain water, yielded warm sepia tones.

The print was finally fixed in a 3 per cent sodium thiosulphate solution rendered slightly alkaline with ammonia.

Palladiotype, Plantinotype. The paper for these processes was purchased ready prepared. The final print consisted of a deposit of platinum or palladium on the paper support.

The negative was printed by contact in daylight and then developed in a solution of potassium oxalate. Development was complete in about thirty seconds. Successive baths of hydrochloric acid were used to clear the print of the yellow stain, and the print was finally washed for about 40 minutes.

Palladium was introduced during World War I when platinum was difficult to get. Both platinum and palladium produced prints with beautiful rich blacks unobtainable with silver. The great advantage of the process was that the image was permanent.

Papers of this type are very sensitive to damp, and special precautions had to be taken to keep them dry after opening the tin in which they were sold. During printing, the paper had to be protected by covering the back with a sheet of rubber.

Owing to the scarcity and high cost of the basic materials, these processes have gone out of use.

Uranium Printing. In this process the action of light reduced uranyl nitrate to a viscous compound. A slightly acidified uranyl nitrate solution (about 15 per cent) was applied to sized paper, printed out, and developed in a 10 per cent potassium ferricyanide solution. A wash in 1 per cent hydrochloric acid completed the process.

Alternatively, silver nitrate might be used for development and deposited silver to produce a grey instead of a brown image.

Powder Processes. Several of these were for a time popular, especially on the Continent. They depended on the discovery that certain substances such as sugar, dextrine, or gum, treated with potassium bichromate, lost their natural tackiness when exposed to light.

A piece of paper or glass so coated after exposure under a transparency or negative and afterwards subjected to a moist air became variously tacky. On dusting with a dark powder this would adhere in proportion to the degree of the action of the light on the hardening of the coating. Plumbago or graphite powder was used and the surplus dusted off. To protect the image the plate or paper was coated with collodion. The same principle, employing certain resins, is still in use in various photomechanical processes.

Pigment Printing. In 1855 Poitevin made photographic prints on paper coated with gelatin mixed with colouring matter and sensitized with potassium bichromate. This was the beginning of the many processes which have led to the carbon printing still practised. The earlier attempts produced only crude contrasty prints. T. W. Swan, in 1864, showed that to retain the more delicate tones the prints had to be developed from the back and, to permit this, devised the single or double transfer system. Since then there has been no basic change in the process, but enormous improvement in carbon tissues with which it is now worked.

A typical pigment process of this type was the ozotype (rendered obsolete by the ozobrome or carbro process) devised by Thomas Manly in 1899. A sheet of bichromate-sensitized single transfer paper was exposed under a negative to give a visible image. It was then applied to a sheet of carbon tissue previously soaked for 1 minute in a solution of 3 c.cm. acetic acid and 1 gram hydroquinone in 1,000 c.cm. water. After drying, the papers were first immersed in cold water for 30 minutes and the pigment image then subsequently developed by dissolving away the untanned gelatin as in the normal carbon process.

In 1905 Manly invented the ozobrome process which eliminated the use of bichromated paper; the pigment image was made direct from a bromide print as in the present-day carbro process (which is an improved version of ozobrome).

Artigue Process. A variation of the carbon process invented by M. Artigue of Paris; it was designed to do away with the necessity of transferring the printed tissue to a temporary support for development. Gum, mixed with any desired colour pigment and sensitized with potassium bichromate, was coated on paper or other support and after exposure under a negative was developed in a soup-like mixture of sawdust and water.

The process was capable of producing very delicate results.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Oil Printing. This process, introduced as a photographic printing method by Rawlins in 1904, was based on lithographic transfer procedures of much earlier date. It depended on the action of light on bichromated but unpigmented gelatin-coated paper. After exposure under a negative, and washing in water, the unaffected areas of the gelatin layer absorbed water and swelled in inverse proportion to their exposure to light. In subsequent application of a greasy ink the swollen areas repelled the ink, while the least swollen ones accepted it most readily.

The pigment image could be transferred to another sheet of paper by pressing the two into contact in a lithographic or a copper-plate printing press. After transfer the original image might be inked up once more and the process repeated for a number of prints. The contrast of each successive print tended to increase up to a point where no more prints of acceptable tonal quality could be made. The type of the original paper and the transfer paper, the character of the ink, and the transfer pressure all had an influence on the quality and brilliance of the transferred image.

As in carbro, the gelatin image could also be produced by chemical action of bichromate on the silver image in the gelatin layer of a bromide print. That process is known as bromoil and is still used by some pictorial photographers.

Chromotype. This was a curious process described by Robert Hunt before a meeting of the British Association in 1843 whereby either a negative or positive image could be obtained depending on the length of exposure, the latter presumably relying on solarization. Describing it, Hunt says: "One drachm of copper sulphate is dissolved in half an ounce of water and to this is added half an ounce of a saturated solution of bichromate of potash. This solution is applied to paper and when dry is exposed under a negative or positive to bright sunshine. The image first changes to a dull brown and, if checked at this stage, we get a negative picture; but if the exposure is continued the brown gives way to a yellow picture on a white ground. If the exposed paper is washed over with a solution of nitrate of silver, a very beautiful picture results." Hunt afterwards added gold chloride to the sensitizing solution and claimed that, according to the degree of solarization, prints could be obtained in crimson, blue, brown or deep black.

Breath Printing. One of Sir John Herschel's interesting discoveries was that latent images could be prepared which could only be seen when breathed on or subjected to a moist atmosphere.

Paper was coated with the dissolved precipitate formed under certain conditions by the addition of silver nitrate to ferro-tartaric acid. Printed under a negative in sunlight the paper so prepared would, by the right exposure, be impressed with a latent image which was not visible unless breathed on or subjected to a light aqueous vapour, when it acquired an extraordinary intensity.

Diazotype. Designed in 1891 for printing photographically on fabrics on which a range of colours could be produced. Prints could be made on paper, but the colours were dull and the whites impure. The term is nowadays applied generally to a number of similar processes.

In practice, the material on which prints were required was first bathed or brushed with a 1 per cent solution of primuline and, when dry, sensitized in a bath of sodium nitrite and oxalic acid. Printing was by daylight (30 seconds to the sun) and the image developed in any one of a number of reagents each of which gave different colour images ranging through red, yellow, orange, purple and brown.

An alternative process used casein instead of primuline for the first solution.

Pinatype. In this process a transparency was made on a soft emulsion of the lantern plate variety and developed in a tanning developer. Alternatively, it could be made on a gelatin-coated plate sensitized with potassium bichromate. The "printing plate" so obtained was bathed for about two minutes in an engraving black or photographic brown pinatype dye; the latter was held in suspension by the gelatin in direct proportion to the extent to which it had been hardened by light action during printing. The plate so charged with dye was then washed free of the surplus dye and finally brought in contact with a sheet of paper coated with plain gelatin. The two were squeegeed together and left for several minutes, when the dye in the printing plate was transferred to the virgin gelatin and, when separated, the latter bore the dye image. Any number of prints could be made by dyeing-up the printing plate and repeating the imbitition process. C.D.

PRINT LIBRARIES. The principal source from which prints can be obtained are the photographic agencies. Names and addressees of these are to be found in directories published for the use of journalists. In addition, the larger newspapers and pictorial magazines usually have a department which supplies prints, not only of pictures which they have published, but also of other photographs in their files. The bigger agencies and periodicals cover a wide range of material; some of the smaller ones specialize in particular subjects.

The fees charged depend to a large extent on the medium in which the print is to be reproduced, the type of reproduction right which is offered, the size of reproduction, and other considerations. Some agencies charge a nominal search fee for pictures which are specifically

requested, but which are ultimately not wanted for reproduction.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Following is a list of the principal subjects of which photographs may be wanted with an indication of sources of supply other than photographic agencies.

Aerial views: aeronautical societies: aeronautical journals; commercial air lines; archaeological societies.

Agriculture: agricultural societies; agricultural journals; makers of agricultural machinery; commercial companies growing their own raw materials.

Architecture: architectural societies; architectural journals; housing research organizations; societies for preservation and recording of historic buildings.

Art (paintings, sculpture, ceramics, furniture, etc.): art galleries; museums; art journals; cultural societies; art dealers.

Children: local newspapers and pictorial journals; individual photographers; child welfare societies.

Industry: trade associations; individual companies; large-scale distributors; research institutes; specialized press.

Landscapes: local newspapers and pictorial journals; individual photographers; railway companies; shipping lines; air lines; geographical societies; tourist associations.

Pets: local newspapers and pictorial journals; individual photographers.

Science: scientific societies; scientific journals; professional bodies; research institutes.

Sport: sporting associations and journals.

Personalities: organizations for which the persons concerned are working, including theatrical managements, film companies, broadcasting companies; cultural and scientific societies; direct from individuals.

Zoology (and birds, fish, insects): scientific societies; scientific journals; journals dealing with nature study.

Names and addresses can be found by consulting relevant directories: press directories; directories of museums and art galleries; directories of scientific and learned societies; trade directories; directories of photographers.

If photographs are wanted of anything connected with countries abroad, the press representative at the embassy or legation of that country will usually be willing either to supply prints or to say where they can be obtained. Other sources for photographs of things and places abroad are travel agencies and societies for promoting cultural relations between nations.

Some public libraries have collections of prints which may be borrowed for reference or reproduction and some of them will obtain, on special request, prints of subjects which are not on their own files. Among the more important of such sources are the Central Libraries of Bermondsey (London), Birmingham, Cardiff and Manchester.

Apart from agencies, the most important print libraries in the U.S.A. are the George Eastman House of Photography in Rochester, N.Y., the University Library at the Northwestern University in Evanston, Ill., the Library of Congress in Washington, the New York Public Library, the Library of the Standard Oil Co. of New Jersey, and the library in the museum of the City of New York.

To obtain a print of a photograph which has been published in a newspaper or magazine, a letter requesting the print should be addressed to the art editor of the journal. It is advisable to enclose another letter to the photographer who has taken the picture, since the journal may not be able to supply prints and will have to forward requests to him. N.W.

PRINT QUALITY. This is a term much used by amateurs—and judges of their work—to indicate technical perfection. It is seldom used in professional and commercial photography. In this field, technical perfection is expected as a matter of course even from the most modest establishment—without it the firm would go out of business.

The commercial photographer can achieve consistently high quality for a number of reasons: he uses appropriate equipment; he very quickly arrives at a rigidly standardized technique; his turnover of sensitized materials and chemicals is rapid enough to ensure that they are always fresh; his printing staff do the same job day after day and they almost always print from negatives of good, standard quality.

All these things work for the professional and against the amateur who generally: has to put up with an improvised darkroom and cheaper equipment; does not do enough routine photography to acquire a flawless technique; does not use materials quickly enough to have them always fresh; is constantly experimenting with new materials and processing techniques, papers and print sizes; and prints from a mixed bag of negatives of a wide range of contrasts and densities but without a correspondingly wide choice of paper grades.

Only the rare amateur possesses the necessary patience and technical knowledge to overcome all these characteristic handicaps and turn out, with much labour and many rejections, a single

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

exhibition print that will stand comparison—at least on technical grounds—with the product of the commercial studio. The result has been the appearance in the amateur vocabulary of the term print quality which has been invested with a false aura of magic and ju-ju. Some prints have it, and others, just as mysteriously lack it; some workers are famous for it, others despair of ever being able to achieve it.

In fact print quality is the result of printing a good negative on the right grade of paper in a safely lighted room with the chemicals recommended by the manufacturer of the paper. The result of following this deceitfully simple specification will be a print which makes full use of the tone range of the paper, reproducing the deepest shadow as a pure, intense black and the brightest highlight as white paper. Between these extreme tones there will be a well-marked variety of shades of grey. All sharp lines will be crisply defined; the print will have no trace of fog, the blacks will be of good colour, and there will be no unintentional blur. As a print it will be technically perfect; it will possess print quality.

The defects that most often rob a print of print quality are: poor blacks, wrong tones, fog, and blur. There is a cause and a cure for each.

Poor blacks can result if the exposure is wrong and an attempt is made to mend matters by giving a longer or shorter development time than the makers of the paper recommend. They are also caused by using stale paper or an incorrect developer or one that is either exhausted or at the wrong temperature. The remedy is to develop according to the maker's instructions using fresh chemicals.

Wrong tones may be the result of using a paper that is either too hard or too soft for the negative. Any of the causes of poor blacks outlined above will also ruin the tone values of the print.

Fog is mostly the result of unsafe light falling on the print—either because white light is leaking into the darkroom, or from the enlarger lamphouse or because the safelight is either the wrong colour or too bright, or too close to the print. Other causes of fog are: stale paper, wrong developer, wrong developer temperature (generally too high) and extended development.

Blur may be caused by incorrect focusing or vibration of the enlarger during exposure. The image may also be diffused by dirt or condensed moisture on the lens. F.P.

PRISM. Transparent substance bounded by plane polished surfaces inclined to one another. The simplest form of prism is used to refract light and needs only two polished surfaces, one where the light enters, and the other where it leaves the prism. Reflecting prisms, however, need three or more polished surfaces.

DISPERSION BY PRISM. A prism bends light rays to different degrees, violet rays being bent most and red least. The over-all bending power depends on the refractive index, the difference in refraction for various colours on the dispersive power.

Refracting Prisms. When light rays from a near object point fall on a prism, they meet the surface at different angles, and as the deviation of the ray produced by a prism depends upon the angle between the ray and the first prism face, the various rays of the pencil will be deviated by different amounts. The light leaving the prism no longer proceeds as though it came from a point, so the prism forms an imperfect image.

If the light from the object is white, it is dispersed by the prism into its component colours, the violet light being bent most and the red least. Thus, a small white object looked at through a prism appears as a spectrum with the violet end bent farthest away from the sight line. The colours of the image are the same as the colours of the rainbow, i.e., red, orange, yellow, green, blue, violet.

Refracting prisms are mainly used in spectroscopic instruments.

Reflecting Prisms. Reflecting prisms are often used in place of silvered mirrors because they are free from the disadvantages of back-silvered mirrors which produce a double image due to reflection from the glass as well as the main reflection from the silver. Also a prism is not as delicate and easily tarnished as a mirror made by silvering the front surface of a glass

RIGHT-ANGLE PRISM. A prism with two faces at right angles and the third at 45° can act like a plane mirror, and is optically more efficient, losing virtually no light.

CC-0. Agamnigal. Digital Presevation Foundation, Chandigarh

plate—a type needing frequent resilvering.

The mirror effect is, if possible, obtained by total internal reflection from the surface of the prism. Even in those cases where total reflection is not possible and the reflecting surfaces must be silvered, the prism can be so arranged that no trouble is caused by the reflections from the unsilvered surfaces. Reflecting prisms are used in the rangefinders which are fitted to some cameras and are also used in front of the lens on certain process cameras for reversing the image from right to left.

Prisms of more complex shape are incorporated in eye-level reflex cameras; there the prism reflects the light several times to turn the ground glass screen image upright and right-way round.

PROCESS CAMERA

The printing blocks used in the photomechanical reproduction processes are made from negatives which are exposed in a process camera—sometimes alternatively called a copying camera.

The process camera is generally used for making copies to a reduced, or at most, a same-size scale. It is only very occasionally needed to make an enlarged copy.

Construction. The process camera is a permanent piece of equipment which is bolted down to the floor of the room or carried on runners which are bolted to the floor. The camera consists essentially of two vertical frames mounted on a set of horizontal rails. One frame carries the lens panel and the other the plate holder and process screen. The frames are connected by a square bellows fitted with supports to stop it from sagging when extended. The maximum extension is usually a little more than twice the focal length of the normal lens. This allows for same-size reproduction at full extension.

The distance between the copy and the camera is usually varied by moving the copy holder, depending on the design of the apparatus while the lens panel is moved as well, to adjust the focus.

The lens panel and plate back can be moved by some form of mechanical traversing gear—e.g., a rack and pinion, or worm and nut—operated from behind the camera. This enables the operator to focus the image on the screen without changing his position. (When copying on a scale of 1 : 1 with a 20 × 20 ins. camera, the lens panel may be 4 feet or more in front of the focusing screen.)

Mounted in front of the plate back there is a holder for the half-tone screen. The holder can be moved forwards or backwards to bring the ruled screen to the correct position in relation to the surface of the plate. The screen must be moved out of the way when the plate is loaded into the holder.

An indicator or other device at the side enables the operator to bring the screen back to the original position.

Both the lens panel and plate back are strongly constructed and accurately mounted so that they remain rigidly parallel over the whole range of adjustment. Any distortion produces dimensional errors which are intolerable in this kind of photography, particularly when making separation negatives from coloured originals.

With some large cameras it is usual to have the film or plate holder assembly in the darkroom, and the lens panel and copying board in an outer room under normal illumination. This arrangement makes focusing easier, and enables the film or plate to be inserted in the holder without a dark slide and taken directly from the camera to the processing section.

On more advanced cameras the movements of the lens panel and copyboard may be motor driven, requiring only push button operation at the darkroom end. Other remote control operations may include the aperture adjustment, the angling of the half-tone screen (for example when making successive separation screen negatives or positives) and the operation of ancillary gear.

Focusing is usually controlled by percentage focusing charts in connection with graduated scales or tapes on the lens and copyboard movements. For a given scale of reproduction it is then only necessary to set the lens panel and the copy board to the figures derived from the percentage focusing charts. This automatically ensures maximum sharpness of the image.

Some process cameras may have automatic focusing systems, based on a cam coupling between the lens and the copyboard movements (rather like an automatic focusing enlarger). This is however rarer and the image sharpness is subject to deterioration through wear and tear—and hence loss of precision—in the mechanical movements.

Highly accurate focusing systems use vernier scales on the camera adjustments to get the image plane in exactly the right position. Sometimes a cable drive for coarse focusing is combined with a micrometer screw drive for fine focusing.

Overhead and Vertical Cameras. Two variations of the process camera construction are the overhead camera and the vertical camera. The former is adopted for very large models, often taking films or plates up to 48 × 48 ins. The copy board and lens board are here suspended from an overhead gantry which carries the track runners for the movement. The camera back with the image plane is usually fixed and may form one end of the gantry support.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SPECIAL CAMERA SYSTEMS: Left: *Highly automated overhead camera for very large original and film sizes (may go up to 50 × 60 and 48 × 48 inches respectively). A, automatic focusing drives and controls, B, overhead rails. C, arm holding lens panel. D, arm holding copy board E, F, focusing screen and film holder. G, control panel for exposure timing etc.* Right: *Vertical camera, usually intended for smaller film sizes but particularly compact in set-up. H, vacuum back for filmholder. J, exposure timing gear. K, crank-driven vertical movement of lens panel and copy board. L, lighting unit. M, copy board. N, supports with guide rails between. O, vacuum pump.*

The main advantage of this arrangement is that the lens panel and copyboard become more accessible than would be possible with the comparatively bulky supports and runners required with a floor mounted camera.

The vertical process camera is by contrast a comparatively compact unit intended mainly for smaller work up to around 12 × 15 ins. The design is derived from that of a vertical enlarger: a vertical stand carries a copy board (which moves up and down on runners), the lens panel (also movable) and the fixed top with the film or plate holder.

The main advantage of the vertical camera is more convenient operation since the image plane is a horizontal surface making for easy loading of the film, and appreciable saving in space. The main drawback is the reduced versatility, both in available scales of magnification and reduction (typically from about 3 × magnification to about 3 × reduction) and in the type of work that can be done. Thus vertical cameras do not usually take ruled half-tone screens, and any half-tone work must be done with a contact screen. Also, this type of camera is rarely suitable for colour separation work.

Focusing and scale adjustment are usually operated by hand wheels or cranks; vernier focusing scales may be provided.

Certain large size professional enlargers can also be used for process work, especially continuous-tone colour separation and making line and half-tone negatives and positives with a contact screen. The enlarger adaptation consists mainly of fitting appropriate film or plate holders and the use of a vacuum easel (possibly with registration pins) in place of the normal baseboard.

Sensitized Materials. Process cameras take plates or films up to 16 × 20 ins. and larger. Glass plates have the advantage of high dimensional stability and are held between a pair of guides which can be adjusted to take any smaller size.

The use of films has become more common since the availability of polyester base materials of much greater dimensional stability than the older acetate film bases. Polyester film still does not reach the stability of glass plates, but film materials are considerably more convenient to handle.

Films are held in vacuum backs to keep them firmly and flat in the image plane. The back consists of a flat plate carrying a number of channels connected to a vacuum pump. When the film is in position, the pump draws the air out of the channels, so that the film is pressed into complete contact with the back. Different channels are brought into operation for the various film sizes.

Film Registration. Punch register methods are used to ensure the exact position of the images on the film so that their images can subsequently be laid on, for instance, litho plates, in precisely the correct positions so that colour separation images are automatically in register.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

UNIVERSAL PROCESS AND REPRODUCTION CAMERA. These cameras take negatives up to 24 × 30 ins. large, and with the copy holder, stand and carriage may weigh 1 to 1½ tons, occupying a floor space up to 15 × 25 feet. Owing to the large size, all controls are usually arranged at or near the rear of the camera. Top left: *Camera set up for working with a process prism, shown against a 1 foot square grid.* Top right: *Front view (with prism in position).* Centre: *Side view (without prism over lens).* Bottom left: *Overhead process camera.* Bottom right: *Vertical camera.*

Connected directly to shutter behind lens.* C, *camera sub-base.* D, *stand.* E, *brake lock for camera carriage.* F, *fine focusing control to camera carriage.* G, *focusing control connected to the front body (i.e., lens board, etc.).* H, *controls for cross front and for rising front movement of lens panel.* I, *fine focusing handwheels (one on each side of camera).* J, *stand.* K, *front body, carrying lens board, prism (when used), and diaphragm control.* L, *prism to reverse image from left to right when required.* M, *diaphragm control scale; automatically sets the aperture to the correct value to allow for different camera extensions and scales of reproduction.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

It is necessary to arrange for various film sizes to be held in punch and pin register and also for contact screens to be pin registered upon that film so that the precise orientation of the screen angles for each colour printing is automatically ensured. This means that it must be possible to punch a piece of unexposed film with the appropriate holes, to register it on raised pins on the vacuum base in the image plane, to hold it by vacuum and then to withdraw the pins to surface level so that the contact screen, which must be larger, can be pin registered and vacuum held upon it.

One of the best known register punches provides two holes about 2½ ins. apart and a slot-shaped hole about 7½ ins. further along the side of the film. One can then have two register pins either the longer or the shorter distance apart upon which one of the holes is fitted and the slot shaped hole fits over the other pin.

It is possible to reproduce, for example, a "flat copy" subject such as a colour painting or a wash drawing, and to introduce into it perhaps a colour transparency, and to colour mask both images. This entails precise register positioning of intermediate continuous tone colour separation negatives, block-out masks (to cover the parts to be occupied by the other picture), colour masks, perhaps introduced lettering, etc., at both the image and the object planes, and further register positioning when the half-tone positives are made.

Some cameras have double-sided film holders for the image plane and for the object plane to allow films or plates to be registered on either side, separated by half an inch or so. One side may contain perhaps the colour transparency and the other a colour mask which can be introduced for part of the exposure and substituted by another for the remainder of the time.

Lens. The lens in medium-sized copying cameras generally has a focal length equal to the diameter of the plate. A lens of shorter focal length is used for making enlarged reproductions when the maximum extension is insufficient.

The aperture is not of first importance because the subject is still, and long exposures can be given virtually at will without risk of movement.

A very high degree of correction is called for, however; in particular the lens must have a flat, evenly illuminated field right to the corners, and be free from astigmatism and chromatic aberration. For colour reproduction it must be fully corrected to bring all the colours to a focus at the same point.

Reversing Prisms. For direct (i.e. not offset) printing the image on the block or printing plate must be reversed left-to-right to give a right-reading reproduction. As the printing plate is normally produced by contact printing a line or screen negative, the latter must thus also be reversed left-to-right as seen through the base. This is exactly opposite to the requirement in normal photography, and such reversal is normally obtained in the process camera by photographing through a reversing prism. A prism is used rather than a mirror because it is easier to achieve absolute flatness and high optical precision in a polished prism surface. The process camera thus normally operates with the prism over the lens, and with the camera body parallel to the copy. The camera can then be swung through a right angle to point directly at the copyboard when it is necessary to use it without the prism.

Where this right-angle alignment of camera and copyboard is inconvenient or impossible, a "straight-through" reversing prism may be used. This is a double prism arrangement which inverts the image but keeps it in the optical axis of the camera system. The focusing and other optical adjustment scales of the camera must of course be calibrated for use with either type of prism.

Copy Holder. The copy is held vertically in a hinged frame similar to a normal contact printing frame. This has a sprung pressure back which holds the copy flat against the surface of the cover glass. The whole assembly usually may be swung into a horizontal position for convenience in loading the copy into the frame.

If the camera itself is mounted on to runners, the distance of the copy holder is fixed; size adjustment is then effected by moving the camera. Cross movement of the copy holder is provided so that the copy can be re-centred when the camera is rotated for operation without the prism.

For convenience, especially when handling flimsy copy (such as tracings) the conventional copy holder may be replaced with a vacuum holder.

Lighting. It is essential for the copy to be evenly illuminated. Carbon arc or mercury vapour lamps are generally used because their highly actinic light makes up for the slowness of the sensitized materials.

The best type of illumination is given by four lamps, two on each side of the board, spaced from each other about 2·5 times their distance from the board. But two lamps may be made to give reasonably good illumination by careful adjustment.

Transparencies to be photographed by transmitted light are normally supported in a masking frame in front of the copy board. The lighting comes from a white surface illuminated by the normal lamps or by a series of tubes for cold cathode illumination fitted behind the transparency.

Exposure Regulation. Fluctuations in the voltage supply to carbon arc lighting can seriously affect the intensity of light; other factors may also cause variation in the lighting. If this occurs during exposure but after the exposure reading is taken, an incorrectly

exposed negative will result. To avoid this the process camera may be fitted with an integrating exposure meter.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The integrating exposure meter, of the photo-electric type, is fitted on to the copy holder so that it receives the same illumination as the copy. The required exposure is pre-set magnetic shutter on the camera. The meter then "adds" the total effect of exposure over time, automatically controlling the exposure received by the plate so that fluctuations in the lighting do not affect the final result. F.P.

PROCESSING MACHINES

Special machines in which films are automatically developed, rinsed, fixed, washed and dried. They operate in a darkroom and are primarily intended for processing large quantities of exposed film. A typical machine for the processing of short lengths can handle approximately 360 per hour. Machines for continuous processing (as in aerial photography) operate at speeds in excess of 4 feet per minute.

Still Films. Processing machines for roll films and sheet films developed out of the requirement of bulk processing in wholesale photo-finishing establishments. Starting from the idea of deep tanks into which films were loaded and transferred in batches, the processing machine in principle features the addition of mechanized transport, timing and temperature control systems.

The machine usually consists of a series of large tanks, containing the appropriate solutions and a suitable system for conveying the exposed films from one to the other. Short film lengths may be suspended from a moving chain driven by suitable gearing so that the films are moved through and lifted from one tank and passed on to the next. Speed of travel of the chain is regulated to give the correct developing time. The time of immersion in any tank can be altered—e.g., by using tanks of differing lengths—to suit the times of processing in the other solutions.

Roll films and 35 mm. films can either hang from bars or be wound round frames. Sheet films are usually supported in special film hangers or frames.

While sheet film processing is normally carried out on a smaller scale in professional darkrooms, not requiring full mechanization, automatic processing machines are used in X-ray departments of large hospitals where the volume of work justifies it.

When continuous lengths of film are used, a slightly different system is employed. The film is fed in and out of each tank over a series of rollers. Times of immersion in each solution are varied by altering the separation between the upper and lower sets of rollers.

The processing of continuous lengths of film is needed for aerial films, microfilm and other material where large volumes of sensitized material of uniform characteristics is processed. There successive lengths of film are spliced together as they are fed into the machine. They then go through the various processing stages, including drying, and are wound up on a final take-up spool. From there the films may be wound off again into their original length, and separated.

In both systems, there is thermostatic control of the processing solutions. The film, after washing, passes through a current of warm air in a drying chamber heated by normal filament heaters or it may pass a series of infra-red lamps.

An alternative system for automatic processing handles the film in batches in a single tank. This is suitable for roll, miniature or sheet film and the batches can vary from half a dozen film lengths up to really big quantities, according to the size of the processing unit installed.

After loading the sensitized material into hangers or other holders for placing in the tank, the appropriate developing and other solutions are pumped into the tank and pumped out again after the required treatment period. The unit contains storage tanks of all the solutions, and one or more pumps plus the necessary pipelines and valve gear to carry the solutions between the individual storage tanks and the processing tank itself. After the processing sequence the film may even be dried in the tank by blowing air through it.

Cine Film Processing. Processing machines for motion picture film are usually larger and more elaborate than for photo-finishing, since they have to handle correspondingly greater lengths of film. For that reason also such machines almost invariably work on the continuous flow principle, with the film passing from tank to tank over rollers. The film is not touched by hand from the point where it is loaded in (straight from the camera spool) until it is wound up on a take-up spool after drying.

Continuous processing machines on this scale frequently also include automatic agitation systems for solutions and automatic replenishment provision. Here replenisher solutions are fed into the individual tanks in previously determined quantities, sometimes with a proportion of the tank stock liquid being drawn off at the same time.

Consistent image quality is particularly important in motion picture work. So frequent quality control tests (short test films exposed under specific conditions) are run through the machine at regular intervals and measured to check the activity of the developer solutions.

In addition to large continuous processing machines for motion picture laboratories, small

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

It is necessary to arrange for various film sizes to be held in punch and pin register and also for contact screens to be pin registered upon that film so that the precise orientation of the screen angles for each colour printing is automatically ensured. This means that it must be possible to punch a piece of unexposed film with the appropriate holes, to register it on raised pins on the vacuum base in the image plane, to hold it by vacuum and then to withdraw the pins to surface level so that the contact screen, which must be larger, can be pin registered and vacuum held upon it.

One of the best known register punches provides two holes about 2½ ins. apart and a slot-shaped hole about 7½ ins. further along the side of the film. One can then have two register pins either the longer or the shorter distance apart upon which one of the holes is fitted and the slot shaped hole fits over the other pin.

It is possible to reproduce, for example, a "flat copy" subject such as a colour painting or a wash drawing, and to introduce into it perhaps a colour transparency, and to colour mask both images. This entails precise register positioning of intermediate continuous tone colour separation negatives, block-out masks (to cover the parts to be occupied by the other picture), colour masks, perhaps introduced lettering, etc., at both the image and the object planes, and further register positioning when the half-tone positives are made.

Some cameras have double-sided film holders for the image plane and for the object plane to allow films or plates to be registered on either side, separated by half an inch or so. One side may contain perhaps the colour transparency and the other a colour mask which can be introduced for part of the exposure and substituted by another for the remainder of the time.

Lens. The lens in medium-sized copying cameras generally has a focal length equal to the diameter of the plate. A lens of shorter focal length is used for making enlarged reproductions when the maximum extension is insufficient.

The aperture is not of first importance because the subject is still, and long exposures can be given virtually at will without risk of movement.

A very high degree of correction is called for, however; in particular the lens must have a flat, evenly illuminated field right to the corners, and be free from astigmatism and chromatic aberration. For colour reproduction it must be fully corrected to bring all the colours to a focus at the same point.

Reversing Prisms. For direct (i.e. not offset) printing the image on the block or printing plate must be reversed left-to-right to give a right-reading reproduction. As the printing plate is normally produced by contact printing a line or screen negative, the latter must thus also be reversed left-to-right as seen through the base. This is exactly opposite to the requirement in normal photography, and such reversal is normally obtained in the process camera by photographing through a reversing prism. A prism is used rather than a mirror because it is easier to achieve absolute flatness and high optical precision in a polished prism surface. The process camera thus normally operates with the prism over the lens, and with the camera body parallel to the copy. The camera can then be swung through a right angle to point directly at the copyboard when it is necessary to use it without the prism.

Where this right-angle alignment of camera and copyboard is inconvenient or impossible, a "straight-through" reversing prism may be used. This is a double prism arrangement which inverts the image but keeps it in the optical axis of the camera system. The focusing and other optical adjustment scales of the camera must of course be calibrated for use with either type of prism.

Copy Holder. The copy is held vertically in a hinged frame similar to a normal contact printing frame. This has a sprung pressure back which holds the copy flat against the surface of the cover glass. The whole assembly usually may be swung into a horizontal position for convenience in loading the copy into the frame.

If the camera itself is mounted on to runners, the distance of the copy holder is fixed; size adjustment is then effected by moving the camera. Cross movement of the copy holder is provided so that the copy can be re-centred when the camera is rotated for operation without the prism.

For convenience, especially when handling flimsy copy (such as tracings) the conventional copy holder may be replaced with a vacuum holder.

Lighting. It is essential for the copy to be evenly illuminated. Carbon arc or mercury vapour lamps are generally used because their highly actinic light makes up for the slowness of the sensitized materials.

The best type of illumination is given by four lamps, two on each side of the board, spaced from each other about 2·5 times their distance from the board. But two lamps may be made to give reasonably good illumination by careful adjustment.

Transparencies to be photographed by transmitted light are normally supported in a masking frame in front of the copy board. The lighting comes from a white surface illuminated by the normal lamps or by a series of tubes for cold cathode illumination fitted behind the transparency.

Exposure Regulation. Fluctuations in the voltage supply to carbon arc lighting can seriously affect the intensity of light; other factors may also cause variation in the lighting. If this occurs during exposure but after the exposure reading is taken, an incorrectly

exposed negative will result. To avoid this, the process camera may be fitted with an integrating exposure meter.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The integrating exposure meter, of the photo-electric type, is fitted on to the copy holder so that it receives the same illumination as the copy. The required exposure is pre-set on the meter which is coupled to an electro-magnetic shutter on the camera. The meter then "adds" the total effect of exposure over time, automatically controlling the exposure received by the plate so that fluctuations in the lighting do not affect the final result. F.P.

PROCESSING MACHINES

Special machines in which films are automatically developed, rinsed, fixed, washed and dried. They operate in a darkroom and are primarily intended for processing large quantities of exposed film. A typical machine for the processing of short lengths can handle approximately 360 per hour. Machines for continuous processing (as in aerial photography) operate at speeds in excess of 4 feet per minute.

Still Films. Processing machines for roll films and sheet films developed out of the requirement of bulk processing in wholesale photo-finishing establishments. Starting from the idea of deep tanks into which films were loaded and transferred in batches, the processing machine in principle features the addition of mechanized transport, timing and temperature control systems.

The machine usually consists of a series of large tanks, containing the appropriate solutions and a suitable system for conveying the exposed films from one to the other. Short film lengths may be suspended from a moving chain driven by suitable gearing so that the films are moved through and lifted from one tank and passed on to the next. Speed of travel of the chain is regulated to give the correct developing time. The time of immersion in any tank can be altered—e.g., by using tanks of differing lengths—to suit the times of processing in the other solutions.

Roll films and 35 mm. films can either hang from bars or be wound round frames. Sheet films are usually supported in special film hangers or frames.

While sheet film processing is normally carried out on a smaller scale in professional darkrooms, not requiring full mechanization, automatic processing machines are used in X-ray departments of large hospitals where the volume of work justifies it.

When continuous lengths of film are used, a slightly different system is employed. The film is fed in and out of each tank over a series of rollers. Times of immersion in each solution are varied by altering the separation between the upper and lower sets of rollers.

The processing of continuous lengths of film is needed for aerial films, microfilm and other material where large volumes of sensitized material of uniform characteristics is processed. There successive lengths of film are spliced together as they are fed into the machine. They then go through the various processing stages, including drying, and are wound up on a final take-up spool. From there the films may be wound off again into their original length, and separated.

In both systems, there is thermostatic control of the processing solutions. The film, after washing, passes through a current of warm air in a drying chamber heated by normal filament heaters or it may pass a series of infra-red lamps.

An alternative system for automatic processing handles the film in batches in a single tank. This is suitable for roll, miniature or sheet film and the batches can vary from half a dozen film lengths up to really big quantities, according to the size of the processing unit installed.

After loading the sensitized material into hangers or other holders for placing in the tank, the appropriate developing and other solutions are pumped into the tank and pumped out again after the required treatment period. The unit contains storage tanks of all the solutions, and one or more pumps plus the necessary pipelines and valve gear to carry the solutions between the individual storage tanks and the processing tank itself. After the processing sequence the film may even be dried in the tank by blowing air through it.

Cine Film Processing. Processing machines for motion picture film are usually larger and more elaborate than for photo-finishing, since they have to handle correspondingly greater lengths of film. For that reason also such machines almost invariably work on the continuous flow principle, with the film passing from tank to tank over rollers. The film is not touched by hand from the point where it is loaded in (straight from the camera spool) until it is wound up on a take-up spool after drying.

Continuous processing machines on this scale frequently also include automatic agitation systems for solutions and automatic replenishment provision. Here replenisher solutions are fed into the individual tanks in previously determined quantities, sometimes with a proportion of the tank stock liquid being drawn off at the same time.

Consistent image quality is particularly important in motion picture work. So frequent quality control tests (short test films exposed under specific conditions) are run through the machine at regular intervals and measured to check the activity of the developer solutions.

In addition to large continuous processing machines for motion picture laboratories, small

scale installations also exist to handle short lengths (100 feet or so) of 16 mm. film. In principle such processes are scaled down versions of commercial units, without however automatic replenishment. Some of these outfits are small enough to stand on a medium-size table.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Paper Prints. The only efficient way of handling prints in bulk is in the form of continuous rolls of paper. Hence automatic print processing machines generally work in conjunction with roll head printers for fixed-ratio enlargements. The machine is of the continuous type, similar to continuous running film developing units. The strip of paper again passes through developing, rinsing and fixing tanks over rollers. The treatment time in any one tank depends on the rate with which the paper passes through and on the length of the paper path inside that tank.

At the end of the processing cycle the paper runs over a drying drum similar to a rotary glazer; this in turn may feed the strip to an automatic trimmer which cuts the paper into separate photographs.

Colour. Colour film processing machines are used mostly in the photo-finishing and motion picture laboratories. In principle they work on the same lines as installations for black-and-white film, but are more complex with a greater number of solution tanks to accommodate the extra processing stages required for colour film. Mostly the machines work on the continuous flow principle, with special attention to temperature control, replenishment and quality control. With colour film the slightest variation in processing conditions leads not only to changes in density but also in colour balance.

A special step required for reversal colour films is the re-exposure stage. Here the film passes between banks of lamps to fog the unexposed silver salts prior to the colour development. (Similar re-exposure stages are also used for processing black-and-white reversal film.) With some types of colour film, having no colour couplers incorporated in the emulsion, a number of selective exposure and colour development stages are necessary to treat each emulsion layer individually.

Colour print processing machines often work with continuous rolls of paper in much the same way as black-and-white roll paper processes. Or they may handle colour prints in batches after loading into print baskets or similar containers.

Automated programming. Modern processing machines handling batches of material (black-and-white or colour) frequently have the timing of the individual processing stages and the transfer of the material from one tank to another controlled by a programming unit. Single-tank processers (in which the solutions are pumped in sequence into one processing tank) employ the programming unit to control the valves and pumping stages.

Basically the programmer is fairly simple. The more elementary systems involve locating the switches (electrically controlled) for the various pumps, valves, etc. at a central point and connecting them to one or more time switches. The latter can then be set for the required duration for every individual processing stage. Once this is set up, the processing machine runs through its programme of operations automatically.

More sophisticated programmers have a scanning unit which reads signals recorded on magnetic tape, embossed into plastic panels or punched into cards or perforated paper tape. These signals in turn close relays which control the various programme functions of the machine. The advantage of this arrangements that it becomes very easy to switch over from one process to another (for example with different types of colour film). This means simply changing the programme—feeding a different tape or a different plastic programming panel through the machine—and changing the processing solutions employed. Some machines may have several programmes built in simultaneously. There the machine contains the solution tanks or containers for the two or three processes for which it is programmed and the sensitive material is passed only through those

CONTINUOUS PAPER PROCESSOR. This processes long strips of prints, wound up in rolls from a roll-head printer. The unit remains in continuous use, fresh strips being constantly spliced on. solutions belonging to its particular processing programme.

One outfit of this kind consists of a series—up to a dozen—deep tanks set up in a circle. Above the tanks runs a circular rail with a motorized carriage. The latter incorporates a lifting motor to raise or lower the batch of films being processed out of or into the individual tanks. A transport motor drives the carriage along the circular rail.

Contact points along the rail, corresponding to the tank positions, stop the carriage above each tank when the contact point is energized. The programming sequence there controls the lowering and raising of the film batches and the intervals between these actions as well as the points (i.e., the tanks) at which the carriage stops for immersing the film batch. Two or three carriages can run on the top rail simultaneously, thus handling several batches in succession before the first one has gone through the processing sequence.

Rapid Access Processing. Automatic continuous flow systems are also used for certain rapid access processes where the fully developed image is required within seconds of being exposed in the camera. Some of the ideas developed for this purpose have also found use in large-scale normal processing machines.

One example is viscous processing, where the thickened developing solution is spread over the film surface as a very thin layer. This remains in contact with the film long enough to complete the development phase and is then washed off by a water spray. Next a viscous fixing solution layer is applied, followed by further spray washing and drying.

Machines of this kind are also used in regular motion picture film processing on a comparatively small scale. L.A.M. & J.D.C.

PROCESSIONS. There are various kinds of processions and each needs a slightly different approach, but in the main essentials all processions are alike in consisting of a number of people proceeding with colourful pomp along a route lined by a great many spectators.

The best known processions are the state occasions when there are probably a number of horse-drawn landaus forming the main centre of interest but followed and preceded by a troop of cavalry and possibly also a detachment of Foot-guards.

The first thing to do is to find out in advance where the procession is going. If the route is not known well it is advisable to look it over in advance to find a good spot to stand. Try to find a place which is slightly higher than the surrounding area. It will permit a clear view even if with a crowd. Having found the right viewpoint, get there early and stay there.

Work out beforehand from which direction the sun will be shining; don't leave it until the day because once the ceremony has begun no spectators will be allowed to cross the street.

Setting-up. Any kind of camera will serve on these occasions so long as it has a convenient eye level viewfinder. Waist level finders are no good because it is essential to shoot over the heads of the people in front. A temporary eye level finder can be made out of a piece of wire bent into a rectangle the same size as the negative. Mount this on top of the camera, parallel to the lens, and then mount an eyepiece made from another piece of wire bent into a small ring with a stalk on it on the back of the camera, parallel with the film plane. The ring of the eyepiece should be opposite the centre of the frame. A reflex camera can be held upside down above the head to gain height.

Having taken up position, take an exposure reading and set the camera, allowing plenty of depth of field by stopping down well. A fast shutter speed is not likely to be needed: no procession travels at speed. Finally focus on the middle of the road and set the shutter.

Subjects. Several kinds of picture may be wanted, but it will not be possible to get them all. Although the whole of the procession may be wanted in one photograph, it is rarely possible to get it. Most streets are too narrow

CC-0. Anandgram Digital Presevation Foundation, Chandigarh

SHOOTING OVER CROWDS. Top left: *A twin-lens reflex camera can be held aloft upside down on a walking stick.* Bottom left: *A tripod screw through the handle of the stick will hold smaller cameras. A bracket on the shaft of the stick will act as sighting device.* Right: *A more elaborate support holds the camera on top of a periscope arrangement.*

to allow inclusion of much more than a section, so under these conditions concentrate on the occupants of the carriages. The closer the better for this kind of picture. But for shots of the mounted cavalry, be either some distance away and include both horse and rider, or as close as possible and shoot against the sky.

Look out for the picturesque costumes of heralds or pikemen in a procession. They make good subjects for close-ups.

If a vantage spot can be found somewhere up in a window overlooking the processional route, it is then easy to include everything in the picture. This may also afford an opportunity to include some of the flags and street decorations which are almost certain to be there. Arrange the picture so that the flags serve to label the scene. For example, a state visit by the ruler of some foreign power might be marked by including his country's flag with that of the nation visited, together with the rulers concerned.

Of course, processions can also include cars instead of open carriages. But there is nothing very interesting in a picture of rows of motor cars, so concentrate on getting as close as possible and then aim the camera through the car window. It will be necessary to open up the aperture by two or three stops to give adequate exposure for the inside of a car.

Gaining Height. The camera may have to be held to look over the heads of people in front. A reflex can be simply turned upside down and held over the head giving a height advantage of a couple of feet. Look up into the viewing screen and continue to face towards the procession. The image will not be inverted and with a little practice it is quite easy to centre it on the screen.

Other ways of gaining height involve a certain amount of manufacturing. The camera can be mounted on the end of a short pole with a piece of string or wire attached to the shutter release. A better method is to use a periscope, preferably not a collapsible type, and mount the camera on top. This provides a method of viewing which is fairly reliable.

In most streets a normal focal length lens will give acceptable image size. If a large image is needed, it is possible to move closer. A view of the vanguard of the procession as it approaches is the only general picture possible in narrow streets where the spectators press closely on to the road. Otherwise it is best to concentrate on close-ups. In wider thoroughfares general views of various units of the procession are easy to get.

If a position is taken some way away, perhaps in a window overlooking the route, use a telephoto lens or attach a telescope in front of the camera lens. This necessitates making a clamp to hold both the camera and the telescope rigidly.

Make some experiments beforehand with this arrangement, to establish the image size produced by the telescope and the minimum aperture for the required depth of field. G.S.D.

PROCESS LENS. The process lens takes its name from the photomechanical processes used in the printing trade. These demand lenses of long focal length in which all the monochromatic aberrations are unusually well corrected relative to the size of the lens. Where colour separation work is required, axial and transverse chromatic aberrations also have to be corrected to a degree beyond anything necessary in ordinary lenses.

Normal achromatic lenses have the ability to bring light of two colours to a common focus, but correction in at least three colours is essential in process work. Lenses corrected in this way are termed apochromatic.

Fortunately, a high lens speed and short exposures are not required and an adequate standard of performance can be provided without undue complexity of lens form at relative apertures in the region of *f* 11. These small apertures give the designer additional freedom to choose the best types of optical glass for achieving apochromatic correction.

Since lens aberrations are not usually stable with radical change of object distance, process lenses are corrected for use over a small range

of copying magnifications and, as a rule, they do not perform very well with distant objects.

Certain photomechanical processes require reversed negatives and this is achieved by placing a mirror or prism in front of, or behind, the lens at an angle of 45° to its axis and pointing the camera at right angles to the object. The mirror or prism has to be inconveniently large if it has to cover a wide angular field from the lens and process lenses are usually designed to cover angular fields varying between 35° in long focal lengths to 50° in the smaller sizes. A coverage of 50° is a wide angle in process lenses.

Large copy and large negative sizes are unavoidable in process work so that focal lengths of these lenses are considerable, reaching a maximum at about 70 ins.

Where the range of conjugate distances only varies slightly from unit magnification, perfectly symmetrical lens forms are adopted. When such lenses are used at unit magnification this symmetry automatically provides perfect correction of coma, distortion and transverse chromatic aberration. Lenses intended for use over a wider range of conjugate distances and some lenses covering wider fields are rarely of the symmetrical form.

Process lenses can also be used for other jobs of a similar nature. G.H.C.

See also: *Lens history; Process camera.*

PROCESS PLATE. Slow plates with a very contrasty emulsion used for copying and photomechanical reproduction. Process plates are usually blue-sensitive only, although both orthochromatic and panchromatic process plates of a variety of speeds and spectral sensitivities are used in colour reproduction of line and tone originals.

See also: *Negative materials.*

PRODUCTION OF PHOTOGRAPHIC GOODS. The production of photographic equipment and materials is undertaken by manufacturers in more than twenty countries of the world, although the greater part of output is concentrated among the more highly developed nations.

In the last decade the expansion of photography in all its aspects coupled with rising economic prosperity, particularly in the United States and Europe, has resulted in an ever-increasing demand for photographic goods, and has served to stimulate established producers and attract new ones to the scene. The increase in both the value and range of equipment and sensitized materials produced has been rapid in recent years (in some cases, notably Japan, spectacularly so), and photographic manufacturing has gained a position among the recognized growth industries.

An objective assessment of the photographic industry is, however, often rendered difficult by the interlinking in many countries of producers with other manufacturing activities. Thus the production of equipment is nearly always to be found in conjunction with optical and scientific instrument making, whilst sensitized materials are frequently manufactured by firms engaged in papermaking and the chemical industry.

A further difficulty, now gradually being remedied, is the general lack of published statistics and other information relating to production and trade in photographic goods, and also the problem of comparability of the available data between countries.

The total production of photographic equipment and materials in Western countries is estimated to have been in the region of £950 million in 1963, and of this figure over 95 per cent was accounted for by manufacturers in seven countries; Belgium, France, West Germany, Italy, Japan, the United Kingdom, and the U.S.A.

The United States is the world's largest producer of photographic goods, some two-thirds in value of whose output is composed of sensitized materials, followed by West Germany and Japan, whose principal interests lie in the equipment field, whilst Belgium, France, Italy, and the United Kingdom are predominantly concerned with sensitized products.

Recent years have seen the growth of links between the chemical industry and photographic sensitized goods producers. Consolidation has been taking place, often by way of mergers and take-overs, and has resulted in the formation of several large international manufacturing groups, each backed by considerable financial and technical resources.

This movement has been particularly marked during 1964, with the linkage of Agfa (Germany) and Gevaert (Belgium), the acquisition of Bauchet (France) and Ferrania (Italy) by the 3 M's Company (U.S.A.), the association of ICI (Britain), Ilford (Britain), and Ciba (Switzerland), and the take-over of Schleussner (Adox) (Germany) by DuPont (U.S.A.). It is partly associated with the desire for manufacturing and marketing facilities within the E.E.C. (European Economic Community), but more particularly with the economies of scale in the production of sensitized film and paper and the high cost of research, especially among colour materials.

Equipment manufacturing on the other hand has continued to be carried on by a large number of independent producers, established principally in West Germany, Japan, and the U.S.A. There are few groupings of any size to be found, apart from the Kodak organization and the Zeiss Foundation, since the production of photographic apparatus can easily be undertaken on a small scale and without necessarily needing highly skilled personnel. Many firms in fact simply purchase individual parts such as lenses, shutters, and lightmeters

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

WORLD PHOTO PRODUCTION AND EXPORT. The bars compare the value of the world production of apparatus (stippled) and materials (shaded) for 1959 (white background) and 1963 (black background). While the photo industry has expanded in all countries, Japan showed the fastest rate of growth—particularly in apparatus where production grew nearly 2½-fold during the period covered. After the U.S.A., the biggest producers of sensitive materials are the United Kingdom and West Germany. The Eastern bloc countries in this diagram include East Germany and the U.S.S.R.

from specialist producers and assemble these and other components in their own workshops.

Mention may be made of the Eastern Bloc countries, whose photographic industries are not large but are nevertheless gradually growing in importance.

The two leading producers are East Germany and the U.S.S.R.; the former having had the benefit of gaining the major part of the established (although severely damaged in the war) German photographic industry following the country's partition, whilst the latter has gradually built up production over the last thirty years. Both countries undertake the manufacture of cameras and other equipment, and in addition have a fairly large volume of sensitized materials output.

Other sensitized goods producers are Bulgaria, Czechoslovakia and Hungary, each important manufacturers of paper, whilst Yugoslavia and Poland also make film on a small scale. Additionally, photographic equipment is produced by Czechoslovakia, in particular cine cameras and projectors. Jugoslavia and Poland. An interesting newcomer to photographic manufacturing is China, where the small-scale production of still cameras and black-and-white film and paper is now undertaken. It is estimated that the ouput of cameras is at present in the region of 100,000 units per year, the bulk of which are the simpler types of model.

PROFESSIONAL PHOTOGRAPHY. The essential difference between the amateur and the professional photographer is that the amateur undertakes photography for personal pleasure whereas the professional is also concerned with earning his livelihood. The amateur may produce excellent photographs that suit his particular needs, often working without a time limit. The professional photographer, on the other hand, is required to undertake a variety of assignments which must be carried out in accordance with client's requirements.

Scope. The range of professional photography is very wide. One industrial company, for example, may employ a photographer to aid research by such methods as photo-elastic stress analysis, while another company will send their photographer to out of the way parts of the world to make records for public rela-

tions or advertising. The photographer may work in a research laboratory, a coal mine, a hospital, a museum, a test farm, in an aerodrome or in the water. He may work amid luxury in a fashion studio or amid dirt and heat in a steel works. He may be occupied in photographing fine buildings, deciphering ancient manuscripts or taking portraits in a studio.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The professional photographer may choose to work for an employer in one of these fields or many others, and with adequate basic training, and continued study he can become a specialist in one branch—e.g., historical research, shipbuilding or portraiture.

While many photographers take up such specialized employment, often in charge of departments, in big industries, public utilities, hospitals etc., many eventually decide to practise on their own account.

Here the field of choice is limited virtually to portraiture, commercial, industrial, and advertising photography, photo-journalism and a few highly specialized applications of photography where the demand is proportionately small.

In most of these the professional photographer must be prepared to serve and study an exacting market. And he will need to know about a bewildering range of regulations and practices—e.g., copyright law, purchase tax, factory act requirements, registration of business names, right to photograph, insurance, liability for clients' goods, and what is done or not done, either on ethical grounds or for good business reasons. In this he can obtain a great deal of guidance and help by joining a professional association.

Before purchasing an established business or starting a new one, he should make sure that he possesses: the right temperament, physical and personal qualities; enough skill, training and experience; the necessary artistic and business ability; and finally sufficient capital to buy, equip, and maintain a business.

In all but the scientific and recording applications of photography he must have some artistic appreciation. It is also essential that he should have general business ability, with a knowledge of simple accountancy and costing. In some branches good salesmanship is indispensable. Whether buying or starting a business, he should engage a good solicitor and a good accountant and he would be wise to budget for no income at all during the first year.

Premises. The choice of the site will depend upon the type of work to be undertaken.

The portrait photographer will consider the type of client he wishes to attract. If he seeks to photograph a large number of people at low fees, he must look for the most prominent site in the busiest street in the town, with a good shop window, and he will have to rely on a big turnover to cover the heavy rent. Very careful study of the neighbourhood by observation and local inquiries is necessary because even a particular street may have a good and a bad side.

If he wishes to serve a more discriminating public and provide high quality work he will need to have premises in quieter and more dignified surroundings.

Position is of less importance to a commercial photographer whose premises simply need to be reasonably accessible to business men and have ample space. The latter generally renders a main road site too expensive.

The industrial photographer only requires an office and workrooms, because most of his work will be done away from the premises. He should at the same time equip a small studio, since he will often be asked to undertake a certain amount of commercial work.

For portraiture the premises must be suitable for conversion into reception room, studio and workrooms. The commercial photographer will need more than one studio, or one big enough to take several sets at once, and there must be large doors and plenty of storage space for articles waiting to be returned. If advertising work is undertaken there must be provision for a model's dressing-room.

In leasing a building it is necessary to bear in mind that in most leases the tenant is responsible for repairs and dilapidations and that heavy expenditure may have to be met when the lease expires. Meanwhile decorations and improvements will be necessary, and it is important that the parts of the premises to which the public will have access should be attractive. This is particularly important in a portrait studio, and the photographer, in choosing his scheme of decoration, must bear in mind the type of client he wishes to attract.

Finally the buyer should take into account that he may in time wish to expand, and it is important to know whether there is room for such expansion.

Security of tenure is of the utmost importance. A short lease is valueless unless it carries an option to renew. An established business with a very short unexpired lease should only be purchased if arrangements can be made with the owner of the property to secure an option for renewal or to take out a new lease.

Equipment. In buying an established business, the photographer is likely to find that some of the equipment may be out of date and capital will have to be available for new equipment.

Some reserve capital is desirable in commercial photography to cover the amount which will always be outstanding in model fees and hire of equipment and apparatus which may not be paid for some time.

Goodwill. When an established business is purchased, goodwill may be worth very little. The goodwill of a popular business in a main thoroughfare may have some value, but an individual business which has been built up on the personality of the outgoing photographer may have little goodwill. There is no

standard by which to judge the purchase price. It is currently held that a business may be worth one year's gross takings or three years' net profit, but it is very important to know whether the takings of the preceding years give a true valuation of normal business.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

When purchasing a business it is important to include in the contract a clause which will prevent the outgoing photographer from practising as a photographer within a reasonable distance for a specified time and taking the goodwill with him.

Fees. Every business should adopt some system of simple costing, and advice in this respect should be sought from a qualified accountant. The Institute of Incorporated Photographers publishes a guide to professional fees for commercial and industrial photography, and also a schedule for reproduction fees.

Social Contacts. It is not enough just to buy a business. The photographer has to become known and respected in the district where he makes his living. So he should take an active part in the social life of the community.

He must also pursue cultural development. The camera is only a tool, but because the technique of photography is complicated and fascinating, many remain obsessed with it. That is not the way to success. The photographer must constantly broaden his outlook and develop his sensibility. He should be able to converse easily with a variety of people on a variety of subjects. There is, too, an ethical standard to maintain. He must command the respect not only of the public but of his fellow photographers. A.F.B. (J.L.A.H.)

PROGRAMMED SHUTTER. Shutter with a continuous range of exposure settings obtained by interlinking the lens aperture and shutter speed adjustment, yielding one exposure combination at each exposure level. A programmed shutter does not provide alternative aperture speed combinations at a given exposure level. Shutters of this kind are usually fitted in electric eye or fully automatic cameras.

See also: *Shutter.*

PROJECTION LAMP. Special high intensity light source designed to conform to the requirements of projection systems.

See also: *Carbon arc lamp; Filament lamp; Lamp caps and fittings; Light sources; Point source lamp; Projection principles.*

PROJECTION LENS. The principal differences between a projection lens and a photographic lens is the result of their completely different conditions of use. Projection lenses are corrected for colour aberrations to suit the spectral sensitivity of the eye and the character of the light emitted by projector lamps, whereas camera lenses are corrected to suit the panchromatic emulsions used in photography. The projection lens is also used in conjunction with an illuminating system which may focus heat as well as light on the lens, so it must not incorporate any delicate cemented surfaces or unstable components. Again, there is rarely any need for a projection lens to cover a wide angular field, but the demand for high levels of illumination on large viewing screens calls for lenses of wide relative aperture.

A large proportion of the projection lenses now in general use have been developed from the early Petzval lens form originally designed as a portrait lens or from an early form of microscope objective designed by Lister. Both the Petzval and Lister types consist of two widely separated doublet lens components and they are similar in performance. They are both capable of providing relative apertures wider than *f*2 but their field of view is restricted by vignetting and poor definition in the outer parts of the field.

Calculation of Focal Length. The focal length of the lens required for any combination of film size, screen, and length of throw is given by the equation:

$$F = \frac{U}{M + 1}$$

where M is the optical magnification (obtained by dividing the width of the required screen picture by the width of the object or film to be projected) and U is the distance between the projection lens and the screen.

This calculation will give the focal length of the required lens, but in practice it may turn out that none of the available lenses of that focal length has a wide enough covering power. When that happens, the focal length must be increased either by increasing U or decreasing M.

For example, a 16 mm. film (width about 0·4 in.) has to be projected to give a picture width of 5 feet (60 ins.) on a screen 12 feet from the lens. The magnification $M = 60/0{\cdot}4 = 150$. So, from the formula, the focal length of the lens (in inches) $= 144/(150 + 1) = 0{\cdot}96$—i.e., a 1 in. lens. But this value of focal length is only twice the diagonal of the 16 mm. film image to be projected, and in such a lens a high standard of definition at a relative aperture wider than *f*2 is not possible with Petzval or Lister type construction. If only these forms are available the focal length must be increased to at least 1½ ins. by accepting a screen picture width of less than 40 ins. or by increasing the screen distance to more than 19 feet for a greater screen width.

Covering Power. As a very general rule the angular coverage of Petzval and Lister type lenses can only be increased by reducing the relative aperture. A lens with a focal length of approximately twice the diameter of the film

image will not usually cover the whole of the area unless it has an effective aperture of $f3{\cdot}5$ or smaller.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

If the lens must be designed for a larger aperture than this—i.e., so that it gives a more brilliant screen picture—then the focal length must be increased to three times the diagonal of the film image, or more.

Where the lens must have a short focal length in situations where the screen distance is limited, it is necessary to utilize special projection lenses developed from various forms of photographic anastigmat lenses. These alternatives are usually of the Cooke Triplet or Tessar constructions and permit the selected focal lengths to be between one and two times the film diagonal.

Relative apertures of such lenses vary between $f4$ and $f2{\cdot}8$; they sometime replace Petzval type lenses when these medium apertures are acceptable and cost of manufacture has to be kept down.

Alternative Constructions. Whilst fundamental differences between the two constructions prevent projection lenses from being used as photographic lenses, a photographic lens can sometimes be used satisfactorily for projection. But caution must be exercised in using complex lenses in this manner. The damage done by the heat of the projection lamp is not always obvious except by photographic testing and repairs (possibly involving separation and re-cementing) can be costly if the original standard of performance is to be restored after such damage.

Other more complex anastigmatic photographic lens constructions have been considerably modified and developed as projection lenses for special applications requiring a very high standard of definition under critical conditions—e.g., wide-screen cinema projection.

These lenses are more expensive than the normal types, but they have the wide relative apertures necessary to provide adequate illumination and can compete with the good central definition of the Petzval or Lister type. Their ability to maintain such a high standard at the edges of the picture as well as at the centre more than justifies their cost. G.H.C.

Zoom Lenses. Variable focus lenses are sometimes used on projectors. The majority of such projection lenses have been designed for 8 mm. cine projectors, with a comparatively smaller number for 16 mm. projection and for still projectors.

Because of their relative mechanical simplicity most zoom lenses for projection purposes have been of the optically compensated type. This type of zoom lens provides a change of focal length by the equal linear movement of at least two components, these being moved in tandem with respect to fixed members, by a simple slide mechanism. Such an arrangement yields a slight variation in position of the focal plane through the focal length range but this is of little consequence in projection where adequate facilities exist for fine focusing. Mechanically compensated zoom lenses also exist for projection.

The main advantage of a zoom lens for projection is flexibility. A single lens can be used over a varying range of projection distances and screen sizes without requiring exact positioning of the projector. Once the projector is set up the lens may be "zoomed" until the screen is adequately filled. Among lenses of this kind, a zoom ratio of maximum focal length to minimum focal length of about 1 : 3 or 1 : 4 is quite usual. P.A.M.

PROJECTION PRACTICE

The projection of transparencies and cine films is one of the post important media of entertainment, education and instruction. The applications on the entertainment side range from amateur slide shows presented in a largely casual manner to the commercial cinema. The scope of educational applications extends from individual slides and short cine film lengths presented in the course of a lecture to illustrate specific points, to completely organized slide lectures with recorded commentaries, and to specially planned and made educational motion picture films.

In both cases the main value of projection is that it makes pictures available simultaneously to group audiences. Further, a positive transparency (including in this context a positive cine film) can be the most satisfying form of photographic reproduction because it can present a greater range of tones than any print made on an opaque base. The maximum contrast range of a glossy black-and-white print is limited by the ratio of the brilliance of the whitest parts of the paper to the blackest deposit of silver in the shadows area of the image. This ratio is never greater than about 30:1, while the contrast of a correctly processed transparency may range from areas of completely opaque silver to completely clear film.

Still and cine projection have in common certain requirements of projection conditions, such as the preparation of the (darkening or blackout, etc.), the screen and the seating arrangements for the audience. They may differ appreciably in the organization of a show, depending on the type of picture presented and on the audience and the purpose of the presentation.

PROJECTION CONDITIONS

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The projection room and the screen are as important as the projector if the transparencies are to be seen at their best by everyone present. Apart from the obvious requirement that the room should be big enough to seat everyone in reasonable comfort, it must be as dark as possible and well ventilated.

The Blackout. It is possible to show pictures in a normally-lighted room by using a very powerful projector and a screen of high reflecting qualities, but the results are incomparably better if the room is really dark. This can easily be demonstrated by projecting a colour slide in a room with some windows open to the light. As the curtains are drawn, the picture grows steadily brighter and of better quality, but there is an almost magical change as the last rays of extraneous light disappear.

It is not always possible to black-out the projection room completely, especially in halls where exits have to be indicated. But there must be no source of outside light in the line of view of any of the spectators, and no rays of direct light falling upon the screen. Even the mere diffusion of the light by thin curtains can make a good deal of difference so long as the windows are completely covered. Dark venetian or pleated blinds are sometimes used. At the same time, it is generally cheaper to provide an efficient blackout than to purchase and run the high-powered projector needed for daylight projection.

As shows and lectures are often held during the evenings and during the winter season there is no great difficulty in making the room dark, but lights outside in the street and from other buildings must not be overlooked. If a meeting is to be held during the afternoon it is always wise to find out if the hall can be blacked out. This is easily overlooked by the organizers, especially if lectures illustrated by slides are not a frequent occurrence. It is possible to project films and slides with fairly bright room lighting, but only to small audiences.

Ventilation. Unless the show is going to be a very brief one, some extra means of ventilation is necessary to compensate for the closing of all doors and windows. The combined effect of the heat from the spectators' bodies and the projection lamp can spoil the show as decisively as poor quality screen pictures. Some form of forced draught, say by one or more extractor fans, is essential in any room used regularly for projection.

This problem is particularly serious when shows are held in comparatively small halls to large audiences. It sometimes helps to request the audience not to smoke, since a heavily smoke-filled atmosphere is not only unpleasant but also absorbs light and so leads to a dimmer picture on the screen.

In the home ventilation problems can be as serious, especially in small rooms used for showing a film or a slide series. Sometimes it is possible to leave a window open behind the curtains which have been drawn to shut out the light. Alternatively it may be necessary to leave a short break at regular intervals during a show for opening the windows and clearing the air.

The Screen. The kind of screen employed has a marked effect on the quality of the picture and on the viewing conditions. A matt white surface reflects the light from the projector over a wide angle, so that even people at the side of the room get a fairly bright view. This kind of screen surface is the only choice where some of the spectators must watch from the side. Beaded and metallized screens give a more brilliant picture, but have a limited viewing angle.

If the projection room is long enough or if there is another room beyond it, a translucent screen can be used to advantage. The image may be directed upon it straight from a projector fitted with a short focus lens, or indirectly by means of mirrors. One mirror corrects the image laterally, and allows the transparencies to be loaded as for straight projection, instead of having to be reversed. The space behind a translucent screen must be as dark as possible, or the image will be faint.

The angle of view of a translucent screen is

BLACK-OUT METHODS. Left: *Roller blind with edge channels to act as light traps. Needs separate means of ventilation, but blacking out the room takes literally only seconds for each window.* Centre: *Thick curtains stretched by wire at top and bottom. Should be several inches larger than the window.* Right: *Pair of overlapping boards placed over window, with air space between them for ventilation. Is particularly suitable for shows of long duration, though it takes longer to put up.*

narrower than that of a matt white and is almost the same as that of the silver and beaded types.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Such a back projection system needs very careful alignment. Back projection units incorporating their own optical systems are easier to set up, but usually the screen size is severely limited and such units are intended for demonstration purposes and presentation to audiences of two or three people.

For a large-size back projection screen a large sheet of tracing cloth or translucent plastic sold for bathroom curtains and similar purposes are usable. Fine linen can be used, but must be wetted before projection to increase the brilliance of the projected picture. The material is best fixed to a frame to keep it flat.

In rear projection set-ups not using a mirror, the slide must be inserted with the spot pointing towards the front or towards the lens of the projector, to ensure that the audience sees the picture the right way round. With cine projectors this is rarely possible (for example reversal of the film in an 8 mm. projector would bring the perforations on the wrong side) so here a mirror must be used. This must be surface silvered of the highest quality and is placed as close in front of the lens as possible.

This form of projection is best when the room is not easily blacked out. The screen should be in the darkest part of the room and shielded from any extraneous light.

With all opaque screens, most of the light is reflected back towards the projectors. If the projector is set at an angle, the light tends to follow the laws of reflection from a polished surface, and the angle at which it leaves the screen is principally the same as the angle at which it meets it.

The brilliance of the image falls off at each side of the optical axis by an amount that depends upon the type of screen used. Before any particular screen is chosen it should always be tried out under actual working conditions.

The size of the screen in relation to the projector needs to be considered as the illuminating power of the projector governs the screen brilliance. If the audience is limited to twenty or thirty people, a projector fitted with a 300 watt lamp or a 100 watt low-voltage lamp will be quite satisfactory. For a larger number a larger screen and higher power will be required, as well as a lens of longer focal length. If the show is to to be a success the audience must be able to see the pictures in comfort. This is not possible when a large number of people are trying to see a picture on a small screen. If the audience is over fifty in number the screen should not be less than 7 × 5 feet. This in turn will need a projector with not less than 500 watt illumination. For larger numbers greater power will be necessary.

For the audience to see and hear under the most favourable conditions, the picture should be projected over their heads from behind the last row of chairs. This has the advantage that it economizes in seating space, since the best position for viewing in the centre is not taken up by the projector, and it avoids leaving a central gap to keep the screen clear. With the projector low down, heads are apt to appear as a silhouette on the screen, while people behind the projector find their view spoiled by stray light, and possibly by the movements of the operator. The projector should be placed about 5 feet high, and the screen arranged so that the lens is opposite the centre. This will also avoid the necessity for tilting the projector, with the risk of loss of definition and the introduction of a degree of distortion.

TILTING THE PROJECTOR. Top: *Tilting the projector upwards will distort the image shape.* Upper centre: *Tilting downwards has the same effect but in the opposite direction.* Lower centre: *If a tilt is unavoidable, the screen should be tilted as well, which will square the image again.* Bottom: *A slight tilt on a long throw is permissible, as the distortion is small.*

Seating Arrangements. The seating must be arranged so that the screen can be seen by everybody clearly and without strain. The shape of the room and position of projector and screen do not always lend themselves to a good seating plan, but where possible the following recommendations should be followed:

(1) The front row should be one screen width or more from the screen—never less. This is the shortest distance from which the eye can take in the whole screen at once.

(2) The back row should be eight screen widths or less from the screen—never more. This is the greatest distance from which the normal eye can distinguish detail without strain.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(3) The plan of the seating should be as narrow as possible to keep the angle of view to a minimum as all screens tend more or less to reflect the brightest picture straight back towards the projector. This requirement is even more necessary with the various types of beaded screen. Where a wide arrangement is unavoidable, it helps to curve the rows towards the screen at each end, so that people sitting out at the edge can look straight at the screen.

(4) The seats should be staggered so that any member of the audience looks between the heads of the people in the row immediately in front. In a long hall or projection room the rear rows should be raised if possible. Raising the screen improves the view of the people at the back, but those in front have to strain up at an uncomfortable angle.

Electrical Preparations. Proper electrical connections are important both for the reliability of the projector operation and for safety. The current supply should always be taken from a power socket and not a lamp holder, and flexible leads run overhead from the wall to the projector to keep them safely out of the way. If this is impossible, run the wires under a carpet or if necesssary under a fixed conduit to stop people people from tripping over and—more serious—sending the projector crashing to the floor. Avoid make-shift electrical connections and make sure that the supply is correctly fused for the projector.

SEATING FOR PROJECTION. Top: *Projector raised and level with screen. The projected beam clears the heads of the audience, but some seating space is lost behind the projector.* Bottom: *Emergency arrangement with tilted projector, resulting in loss of seating space in front of the projector as well as behind. The screen should be tilted.*

CLASSROOM PROJECTION. Top left: *School desk used as projector support with lid raised by books.* Top right: *Projector on demonstration bench, permitting operation by teacher. Screen may have to be oblique to projector axis.* Bottom: *Corner projection in a classroom. Screen may always remain in position without obscuring blackboard.*

A spare lamp and fuses of the correct rating should always be kept handy.

Check also that the current supply is of the same voltage as specified for the projector. This is particularly important with the projection lamp; overrunning a lamp gives brighter light but drastically reduces the lamp life. Underrunning cuts down the image brightness and also affects the colour of colour transparencies or films. Some projectors have a voltage adjustment; this should be set to the available mains voltage. With still projectors voltage variations may affect the speed of the fan and possibly of the slide change; this is not serious. With cine projectors they may also influence the speed at which the projector is running.

SLIDE SHOWS

Owing to the current popularity of reversal colour films, sets of colour slides and a projector are to some extent replacing the photo album as a means of showing one's pictures to friends, etc. At the same time the projector remains an important aid to illustrating lectures and talks. Requirements of the two applications are parallel, though not identical.

Home Projection. The informal slide show needs comparatively little preparation beyond darkening the room and arranging seats for the people watching the pictures. Be sure to prepare

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the slides, stacked up (or loaded into a magazine in the case of a magazine projector) in the right order and correctly oriented. Where slides are loaded individually into the projector by hand, the identifying spot on the slide must be in the top right hand corner facing the operator behind the projector. With a single-slide manual loading projector every slide must be individually checked for orientation in this way before insertion.

With magazine projectors this preparation can be done beforehand while loading the magazines. Here it is particularly important to check the orientation, since the correction of a wrongly loaded slide in the magazine usually requires removal of the whole magazine from the projectors. On a few models individual slides can be removed while they are in the picture gate for rectification; however this procedure is still obvious to the audience.

With a manual slide projector the projectionist usually has to sit more or less on top of his machine to operate the slide change. Automatic slide changing by remote control is more comfortable for the projectionist and also improves the smoothness of the show. The operator can then sit among the audience and only has to handle the operating button at the end of the remote control cable.

Where card mounted transparencies are being projected the image is liable to "pop" in or out of focus on the screen as the film changes its plane in the card frame. This requires constant refocusing as each new slide is projected. Since that procedure is somewhat cumbersome, it is usually more convenient to focus the first slide after it has "popped" and wait until every successive slide pops into focus rather than readjust the lens setting every time. This takes a few seconds.

Refocusing is simplified with a remote control system that also includes remote focusing, but still remains a job to be done with every new slide.

Transparencies mounted between glass in plastic or other frames are free from this trouble and, provided that all mounts are similar, it is only necessary to focus the first transparency sharply. All the rest will then remain sharp on the screen. Some projectors incorporate automatic means of refocusing the image if the plane of the transparency moves.

A home slide show will not require much in in the way of elaborate commentary. This may be quite informal, though repetitive descriptions like: ". . . this is Jane by the Leaning Tower of Pisa . . . and this is the Colloseum in Rome . . . and this is Vesuvius near Naples . . ." are apt to be monotonous. (The same applies of course to "explanations" accompanying the showing of a photo album.)

The Slides and the Projector. The projector should be suitable for the type of transparency being shown, especially as far as the format is concerned. Most amateur transparencies are of the 24 × 36 mm. size, mounted in 2 × 2 ins. slide frames. Most projectors will also take super slides with an image area of $1\frac{5}{8} \times 1\frac{5}{8}$ ins. (in similar 2 × 2 ins. frames) but some need a change in the condenser. Half-frame 18 × 24 mm. transparencies can also be shown, though special projectors for this format utilize the light output better. A projection lens of shorter focal length is advisable with half-frame transparencies, otherwise the screen image is very small.

The larger $2\frac{3}{4} \times 2\frac{3}{4}$ ins. slides made from size 120 roll film transparencies need a larger projector; some models take both slide sizes interchangably. Big projectors for $3\frac{1}{4} \times 3\frac{1}{4}$ ins. slides are rarely used for home presentations.

It is always worth while to select or process transparencies to be shown in a series so that there are no great differences in brilliance between one picture and the next. This is because the human eye takes some time to accommodate itself to a change in brilliance. So a dense slide following a thin one appears denser than it really is, while a thin one shown after a dark one causes an unpleasant glare.

The first transparencies of the session should be fairly bright because the eyes of the audience will not had have time to become accustomed to the dim light.

Black-and-white slides are at a disadvantage when shown with colour transparencies. They

HOME PROJECTION. Top: *Projecting across the long side of a room, with the screen in a recess if available.* Centre: *Where the long side of the room is not suitable for projection arrangements, oblique projection provides some extra throw, though with a certain amount of image distortion.* Bottom: *Projector leads should be run overhead and out of reach.*

can, however, be improved in this respect by either hand-tinting, toning, staining or binding them up with a coloured filter.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Transparencies in colour have always been popular, even when hand tinted, and today factory-processed colour films have made it far easier to produce a good colour transparency than to make even a reasonably good black-and-white print.

A good colour transparency will stand as much or more magnification than a mono chrome, but some colour systems suffer from poor definition or an unduly assertive reseau which limits the degree of enlargement.

Colour of Illumination. The colour of the viewing or projecting light is of the first importance in projecting colour transparencies. A projection light of the wrong colour can completely upset the colour values of the transparency. With some types of transparency, the manufacturers specify a certain kind of projection light. But this light is only exactly right when it is used with perfect transparencies.

Where the colour balance of the transparency is defective, it can often be improved by the addition of a tinted filter. In some cases it is better to stain the emulsion, or a filter can be bound up with the transparency. In the same way, a filter can be inserted under a transparency in a viewer to improve its colour balance.

The colour of the filter required must be found by experiment; it is usually very pale in colour. Light blue is the most common, particularly in viewers. Suitable filters can be made from lantern plates, fixed out, bleached if necessary, and stained with dyes. Gelatin or plastic sheet can be dyed and used as a filter, and the palest colours of theatre gelatins are often satisfactory.

In showing colour transparencies, not only should the brightness of succeeding slides be approximately the same, but their colour values should also be similar. The more subdued tints and pastel shades should not follow on very bright colours. (When the eyes look at one colour for a time, and it is then removed, they are left with an impression of the complementary colour. This impression tends to superimpose itself on succeeding colours and alter their values.)

It must be borne in mind that the process of seeing colours is a subjective phenomenon. All that can be done is to aim at producing an effect which will please most of the spectators. It is impossible to overcome all individual differences in colour perception and preference.

Second-rate apparatus and poor viewing conditions will often pass for monochrome work but prove quite inadequate for colour viewing and projection. In particular, colour transparencies can only be seen at their best in complete darkness.

Stereo Transparencies. Stereo transparencies are made in various sizes of which the commonest are:

(1) 18 × 24 mm., made with mirror or twin-lens attachments on normal 35 mm. cameras.

(2) 12 × 13 mm., 22 × 24 mm., 24 × 24 mm. and 24 × 30 mm.; all made on standard 35 mm. film in stereo cameras.

(3) 4·5 × 10·7 mm., 6 × 13 cm., etc.; made on larger films and plates in large stereo cameras.

The transparencies may either be viewed in a stereo viewer, or projected by a suitable projection system.

Since it is not practical to project the two images side by side, chiefly owing to the limitations of human vision, they must be superimposed by projection in twin-lens projectors. The necessary separation of the right-eye and left-eye images can be accomplished in two ways.

For the older method, the anaglyph, the two images are toned red and green respectively (or projected through appropriate filters in front of the projection lenses) and viewed through spectacles of corresponding colours so that each eye sees only its appropriate image. The more modern method is to polarize the two projection beams by two polarizing filters at an angle of 90° to each other. The image is viewed through polarizing spectacles the two glasses of which are orientated in the same sense as the corresponding projected left-eye and right-eye images. This is the only practicable true three-dimensionable system of projection for colour transparencies.

Stereo pairs made with mirror attachments on single lens 35 mm. cameras may also be shown on a standard projector fitted with a device on the lens to polarize the two halves of the beam and accessory equipment to superimpose the images. The more efficient method is to project the transparency pairs by means of twin optical systems. Illumination may be from a single lamp, but on account of the light loss in polarizing systems, twin lamps of the highest power are often needed. The polarizer may be adjacent to the transparency or attached to the lens.

The surface of the screen must be of metallic material (e.g. aluminized or aluminium sprayed) which does not depolarize the light.

The taking and mounting of the transparency must be done with the utmost precision to avoid adjustment of the projector, and inconvenience to the spectators.

A position as nearly frontal as possible should be occupied by the viewers, who should not sit nearer to the screen than, say, three times the width of the projected image.

Small back projection viewers for table use have been evolved. Superimposed polarized images are shown in the usual way, and, of course, polarizing spectacles are required.

Pseudo-stereo Projection. An alternative method of simulating a stereo effect with single tran-

sparencies consists of projecting them through a beam splitting optical system. This produces two partially overlapping images on a metallized screen. Polarizing filters in the two projection beams again polarize the two images at right angles to each other. On viewing through corresponding polarizing spectacles a sort of depth effect is obtained. This is because the two images in slightly different positions on the screen induce the eyes to converge less than they would on to a single image in the plane of the screen. A real feature of this depth effect is that the image appears some distance behind the screen (emphasized by having a bold black frame to the latter). The apparent depth effect is most pronounced when objects in the picture decrease in size as they get progressively further away.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SLIDE LECTURES

Where slides are used in connection with a lecture, the lecture and the illustrations must be planned together. A list is needed of the slides available or to be obtained. Each slide must clearly show the point to be made, and it may be necessary to have two or even three. It is not advisable to use colour slides and monochrome together, as one gains at the expense of the other. Preferably colour slides should all be made on the same colour film where possible, to reduce variations of colour quality.

All slides should be of the same size and even of the same transparency format (e.g. all 24 × 36 mm.). Generally 2 × 2 ins. or $2\frac{3}{4} \times 2\frac{3}{4}$ ins. slides are most useful in view of the versatility of projection equipment available for them; the larger $3\frac{1}{4} \times 3\frac{1}{4}$ ins. or similar formats are still used sometimes.

If a magazine projector is used, have the magazines loaded ready beforehand, with all the slides correctly orientated. They should of course be spotted in the standard way.

If the projector is of the older single slide type, the slides are best kept in a transport box with each slide accommodated in a separate groove. This ensures that the slides are kept in a correct sequence and do not slip to the bottom of the box when used. They are also more easily handled by the operator. It is a good plan for such a box to take double the number of slides to be used side by side, so that after use the slide is placed in the opposite empty section. This saves trouble in sorting them next time.

MARKING SLIDE SEQUENCE. A diagonal line across the edges of a series (e.g., a lecture) of stacked slides will show immediately if one slide is out of sequence in a box.

Slide Change and Signalling. Where a projector with manual slide changing (single or magazine type) is used the operator needs some prearranged signal to change the slide. As far as possible the signal should not be seen or heard by the audience. A signal lamp operated by the lecturer at his table is ideal.

Where a magazine projector has remote control, an operator is not always essential. In this case it is necessary to have a projector with a magazine capacity to take all the slides of a lecture. Straightforward remote control cables are usually too short for lecture use where the lecturer may be 20 to 100 feet away from the projector. Direct control devices available for this purpose include supersonic whistles which actuate the automatic slide changing mechanism via an amplifier, and devices that change the slide when the lecturer stops speaking. Radio control is also possible with matchbox size transmitters.

Such remote devices should, however, be able to adjust the picture sharpness as well as change the slide.

Generally it is safer to have an operator in charge of the projector, to deal with breakdowns or other emergencies on the spot. Local government regulations for public halls may make it essential to have a responsible operator for a projector, and incidentally also lay down a variety of other conditions regarding seating, access of the audience to the hall, organization of exits, etc.

Lecture Delivery. Once the illustrations are planned and obtained the lecture should be written out in full.

Next the lecture is rehearsed with the slides, an assistant operating the projector. This will reveal needless duplication or omissions and check the length of time taken for the delivery.

If possible, the lecture should be spoken and not read. Notes are helpful if the lecturer's memory is poor and they lend some confidence to the inexperienced speaker.

For those who are unfamiliar with public speaking here are a few hints:

Make a point of arriving at the hall at least twenty minutes before you are due to start. This will allow you to make contact with the operator of the projector, to show him the slides and their order of projection, and to rehearse the "next slide" signal. It gives you time to meet the Chairman and other officials and all this helps to establish confidence.

When delivering the lecture speak slowly and distinctly. Do not hurry, but on the other hand avoid long pauses. Remember there may be people at the back of the room who have difficulty in hearing. Watch to see if this is so and raise your voice. Keep your head up while speaking.

When it is necessary to indicate some special point on the screen, turn to face the screen, point out the subject, and then face the audience. Torch-type pointers that project a bright arrow on the screen where required, are neater than a wooden pointer.

A microphone can be helpful in a large hall and it gives confidence. In using a microphone it is not necessary to raise the voice above the normal conversational level; in fact to do so defeats its own object. A microphone is also useful if written questions are passed up on paper. The speaker is able to repeat the question and reply to the audience.

Film Strips. A film strip consists of a number of illustrations of the same subject arranged in the correct sequence on a single length of 35 mm. film. This is projected in a projector fitted with a film strip carrier of two spools. The film is wound on one and passed through the projector by winding it on to the take-up spool. This may be done by hand or, on modern film strip projectors, by remote control. Many projectors for single slides can be fitted with a film strip carrier.

While a film strip can be prepared for a single lecture, this is usually cumbersome. It involves selecting the illustrations in the form of negatives or making negatives from existing illustrations. These negatives are then printed in the required order on positive 35 mm. film. Film strips are thus more suitable for set lectures to be given in identical form in a number of places and are more widely used by educational bodies and various publicity organizations.

Sources. Film strips and slide sets are supplied by many sources. There are educational film strips for use in schools, and religious bodies lend slides and film strips dealing with their own particular organizations for education or publicity. Film strips are also issued by various departments of horticulture on subjects such as the culture of various plants and the control of plant pests. Travel agencies and railway and steamship companies also supply sets of slides and film strips with the text compiled by the publicity departments concerned. Photographic manufacturers and national photographic organizations also have numerous slide and film strip lectures available; although usually a written commentary is supplied with these, in some cases a lecturer may attend. Many of these sources are free of charge.

Sound Slide Shows. The commentary to a slide show at home or the lecture accompanying a set of slides can also be recorded on tape and played back together with the progress of the images on the screen. This has the advantage that the commentary can be prepared more carefully and the talk delivered with the best effect, rehearsing and re-recording several times if necessary. It tends to make an informal slide show a little more rigid but also more professional looking.

The presentation can become more versatile and more attractive. Further sound effects may be added as well. Such an automatic recorded lecture lacks, however, the personality of a live performance. It is particularly useful for set lectures and demonstrations to be delivered over and over again, for example publicity demonstrations at exhibitions, advertising lectures and shop or shop window demonstration.

With a tape-recorded commentary or lecture the whole presentation can become completely automatic. This involves a projector with remote control facilities and a tape coupler which links the tape recorder with the projector. The tape carries cueing signals which automatically actuate the slide changing mechanism of the projector.

In use the tape runs over a head on the tape coupler (usually attached to the edge of the tape recorder) which picks up the cueing signal. Some tape recorders incorporate special provision for the recording and the reading of such signals without a separate tape coupler.

The production of a tape-recorder lecture or show needs largely the same kind of preparation as an ordinary lecture, but can be done more at leisure. First select the slides to be used and arrange them in the right order. Then prepare the lecture and write it out in full or—if intended for less formal presentations—at least note down the main headings.

For a formal lecture a full scale rehearsal is usually advisable. Set up the projector with the slides and project them one by one as you read the lecture. This rehearsal will show what adjustments are required either to clarify a point or to shorten an overlong description. It is useful to have a trial audience of one or two people to criticize and indicate what the reaction of a normal audience would be. Mark the points of slide changing on the script.

Run through the slides once more, this time recording the lecture on the tape recorder. Set up the microphone in a convenient position in front of you, adjust the tape recorder controls for the best recording level (with a short trial run) and start again from the beginning, delivering the lecture.

Speak clearly and not too fast, but do not be too nervous about mistakes; these can be corrected immediately by running back the tape a short distance and re-recording. Do not speak too near to the microphone, as this otherwise picks up breathing and other background noises of speech. Remember that a style of a spoken lecture is different from a paper intended for publication in print. Speech should be less formal; avoid long words and complicated sentences. On a printed page the reader can go back over a sentence that does not seem completely clear at first sight; the audience in a lecture must be able to catch every word and every idea presented. For that reason more repetition is permissible in a spoken lecture than in print.

CC-0. Agatharisearch Foundation. Digitized by eGangotri

It is a good idea to time the delivery of the lecture during the rehearsal. Usually it has to run to a specific time and the rehearsal allows any necessary adjustments to be made to the length. The beginning and the end of the talk require particular care. The beginning should make immediate contact with the audience while giving the impression that the lecturer just didn't know how to stop.

CC-0. Agamnigam Digital Preservation Foundation, Chennai

Finally, when the whole lecture is on the tape, record the cueing signals for the slide change. Usually these are on the second track of the tape and so are completely unnoticed by the audience. Check with a first run-through that everything works satisfactorily; the lecture is then ready for presentation.

With informal slide shows less preparation is necessary. If you have a note of the main headings and items to be mentioned relating to each slide, you can go ahead and record the commentary straightaway. Such a free way of talking often makes the commentary run more easily. However if you are self-conscious in front of a microphone, it may be better to write out the text beforehand, or get someone who is an easy speaker to record it.

Again leave the recording of the cueing signals to the last.

Audio-visual Projection Systems. Complete recorded slide lectures are available for a number of educational purposes as well as for instruction and training in industry, as sales aids, etc. Usually these are played back on combined slide projectors and tape recorders built into a single unit, where the slides are loaded into the projector and the tape threaded into an attached tape deck.

Recorded lectures may also be associated with film strip projectors and may then even be recorded on gramophone records which are played back on a suitable combined machine. This makes the mass production of such lectures easy; since the pictures are permanently combined in the predetermined order, it is more convenient to have the sound in a similar permanent form.

Systems also exist where commentaries are recorded for each picture either on adjacent film frames or on special slide mounts carrying a magnetic track. These require projector systems suitable for such combinations, and incorporating the appropriate amplifying and reproduction components. L.A.M.

CINE PROJECTION

The work that has gone into the making of a film culminates at the moment that the film is presented to an audience. Any standard of projection less than perfection will nullify much of its value.

A hackneyed piece of advice which is often ignored, even by professional 16 mm. projectionists, is to have the projector set up and adjusted before the audience arrives. Make sure the screen is tightened and free from wrinkles, and that no stray light is falling upon it from a partially opened window. Make arrangements for the control of the lighting.

Check that the projector is properly aligned upon the screen, and that the lens is clean and in focus. When starting the projector, make sure that the film leader is not projected—cover the lens until the opening title arrives in the gate. After every reel, clean the gate and sprockets before rethreading. Make sure that the spools are not bent.

The projector should be set up on a firm table. Books and other objects for raising the projector height or for tilting it are inadvisable, for the image may shake on the screen. The projector table can also hold the extra reels of film (if more than one reel is being shown), the spares and a splicer. The spares, for dealing with unexpected breakdowns, should include a lamp, motor and take-up belts (where the projector has a belt drive) and fuses of the correct rating. A torch and a screwdriver are handy. The splicer is mainly intended for emergency repairs of film breaks. A tape splicer is best, and the faster it can rejoin the film, the better.

Running the Show. Carefully follow the instructions for threading up the projector. To check the correct orientation of the film lift up the film end so that it points upwards from the feed spool and look at it with your back to the screen. The image (for example the title) should then be the right way up and the right way round. Pay special attention to the film loops when threading the film into the projector and (in the case of a sound projector) round the sound head. Attach the film end to the take-up reel and turn the latter through a couple of revolutions to make sure that the film is secure.

Many modern projectors feature automatic threading. There you depress a button or lever, and simply feed the film into a channel above the gate. The projector mechanism then takes the film through (sometimes even through the sound unit) to emerge at the back for attaching to the take-up reel. On some projectors the film even goes to the take-up reel automatically.

When focusing the image on the screen check that the picture is also correctly aligned in the

FILM ORIENTATION. To check that an 8 mm. or 16 mm. film spool is correctly mounted on the projector, lift up the film end while standing with your back to the screen, and read the title. If this is upright and the right way round, it will project similarly.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

gate; most models have an adjustment to raise or lower the picture so that no frame line is visible on the screen.

Focus while the projector is running rather than when set for still projection; the position of optimum sharpness may not be the same in the two cases.

If the projector has a zoom lens you can at this point adjust the image size to fill the screen; otherwise you have to move the projector nearer or further away from the screen. Needless to say, all this should be done before the start of the show.

When everything is ready, switch off the room light and start the projector running. For a really professional-looking set-up you can use a dimmer. Some projectors have a switch built in for controlling the light; otherwise have just a small table lamp burning near the projector while the rest of the room lights are switched off, and turn off this lamp as the film starts running.

Always start the motor before switching on the lamp. On most projectors the same switch operates the two, and has two positions to start the motor first and the lamp afterwards. If you are projecting several reels, wait with rewinding the individual films until the end of the show. To change over, put the feed spool on the take-up shaft and the new reel on the feed shaft, then thread up as before and continue running. Keep only the pilot lamp near the projector switched on for this purpose, unless you want to make an interval in the performance.

A non-stop show of several reels is possible in two ways. One is to have two projectors and load them with alternate reels. While the first projector is running the second one is loaded up, and switched on as the film runs out on the first machine. This switching over needs a little practice and a knowledge of exactly what happens at the end of the film reel. Always switch off the finishing projector before the trailer goes through the film gate.

If both projectors are lined up on the screen simultaneously you can even switch on the second machine and start it running two or three seconds before the film is finished on the first. This lining up needs care to ensure that the result is a dissolve from the one picture to the other, quite a good effect unless there is an intentional lengthy fade. If you are not very skilled in switching over, simply switch off the first projector as the film comes to its end, and switch on the second one. The pause need only last a second or two and is virtually unnoticed.

Twin projectors can also be mounted on a sliding base, so that the first projector is moved out of the way as it has finished its job and the second one moved into place.

Non-stop multi reel shows with a single projector are a little more involved, since they require the splicing of the film (a temporary splice is adequate) while the projector is running. For this the last 50 or so feet of the film must be pulled off the feed reel while the projector is running, spliced on to the beginning of the next reel, and the latter put in place. The loose loop of the film is best kept in a film bin, and this procedure needs care to avoid twisting the film. It also requires practice to be able to do the job quickly yet safely without panic.

Sound Film Shows. There are three main ways of showing cine films with sound accompaniment: playing music or other effects on gramophone records or a tape recorder, synchronizing sound on a tape recorder with the projector, and projecting an optical or magnetic sound film.

The sound reproducing equipment (amplifier, etc.) is usually built in to the apparatus used. The loudspeaker, where separate, is best positioned above the screen. Two speakers on either side of the screen are better still, as they distribute the sound more evenly, especially in a large hall.

The speaker should not be too low down. Otherwise the sound may be too loud for people sitting in the front seats and too weak for people at the back. If the auditorium (e.g. a large hall) is too reverberant it may be necessary to hang up blankets or carpets to deaden sound reflections. Such reflections are, however, likely to be less prominent when there is an audience than in the empty hall. In the home, sound echoes are less likely, but aim to hold shows in rooms with a carpet.

An almost invariable fault of projection, other than in the cinema, is to have the sound too loud. In a hall it is impossible to judge the quality or volume of the sound when standing by the projector; it is better to have it monitored by a person in the centre of the seating area.

Gramophone Records. Music on gramophone records can be used to accompany silent films. For home projection a simple record player is perfectly adequate, and a 12-inch record at 33⅓ r.p.m. lasts long enough for a 400-foot length of 8 mm. film or 800 feet of 16 mm. (at 16 f.p.s.).

Silent films of greater length are rare, but you may want to change records even during a film to have a selection of different music pieces. In that case a double turntable is useful with separate volume controls. To change over from one record to the other, lower the second pick up on the record as the first record nears its end or the point where you want to stop. Mix from the first to the second by means of the volume controls. Have the records prepared beforehand; when playing selected portions from a record, a guide for the pick-up to enable it to be lowered at a specific point is useful.

A tape recorder is even more versatile and can be used for playing pre-recorded tapes. Or you can record a tape specially for the film. This may consist of selected items of music combined with a commentary. Keep the latter reasonably general rather than directed at specific scenes requiring accurate timing. Otherwise it becomes difficult to keep the tape and the film syn-

chronized without proper synchronizing equipment. Since tape recorders can run up to an hour even at tape speed of 7½ ins. per second (and twice as long at 3¾ i.p.s.) no tape changing need be involved during a film show.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

When gramophone records or commercially available pre-recorded tapes are used in public or semi-public film shows, fees may be payable for performance rights (for example to the Performing Rights Society in Great Britain).

Synchronized Sound. When projecting a film carrying an optical or magnetic (stripe) sound track, the only problems involved are keeping the sound level (and, if possible, quality) under control. With optical sound films—i.e. with a photographic sound track printed along side the film edge—the sound and picture are indissolubly wedded together. The sound is got on to the film by printing of a sound track derived from a magnetic tape recording. This usually requires the services of a professional recording studio and laboratory.

When projecting an optical sound film, the projector almost invariably runs at 24 f.p.s., and this is also the standard running speed of the film in the camera.

Careful threading of the sound projector is important to ensure that the length of the film between the gate and the sound head corresponds to exactly 26 frames (on 9·5 and 16 mm.) according to the internationally laid down standards. The sound corresponding to any given frame on the film is thus recorded 26 frames ahead of the picture. This is necessary because the film runs through the projector gate in jerks, but must run smoothly past the sound head. These two opposing requirements cannot be achieved at the same time (and there is in any case no room for the sound head in the projector gate) so the two functions must take place on different parts of the film.

The sound track on a striped film (8 or 16 mm.—also possible with 9·5 mm.) is again permanently wedded to the film. The procedure in projection is much the same as with optical sound, but the projector must of course have the appropriate magnetic heads. The separation between the picture and the sound is here 28 frames for 16 mm. (and also 9·5 mm.) film, and 56 frames for 8 mm. The standard speed of the film through the projector is again 24 frames per second (in all gauges), but 16 f.p.s. can also be used.

A sound track recorded as the slower speed is somewhat inferior in quality (especially in 8 mm.), and cannot be played back on a projector running at any other speed. Sound recording at 16 f.p.s. is useful only if sound has to be added to silent films shot at that speed. When making a film destined for sound projection it is better to stick to the standard sound running speed in the camera. Many magnetic sound projectors can run at either 16 or 24 f.p.s., but a few are limited to 24 f.p.s.

The main feature of striped films is that you can record the sound on the film yourself. With commentary and even music effects this is fairly simple: you record the sound while the edited film is being projected. On most projectors the sound heads can be used both for recording and for playback. The same applies to the various sound adaptors which attach to many 8 mm. projectors to permit the projection of striped film.

Dialogue and live effects are a little more tricky, and these should be available recorded separately on tape. They then have to be mixed into the sound track on the film, a matter which requires accurate timing. However if the recording is not quite right the first time, you can erase and record again on the magnetic stripe.

During projection take special care to see that the controls are set for playback and not for recording, otherwise the record may be erased accidentally. Many sound projectors have special interlocks and warning signals.

Projection with Tape Couplers. There are four main systems of linking a tape recorder with a projector for running the tape and the film in synchronism.

The first uses an attachment fitted to the tape recorder. A loop of tape is run over a capstan and a movable arm connected to a variable resistor. The capstan is geared to the projector motor by a mechanical coupling. The loop arm is spring loaded and moves forward or back according to whether the tape speed increases or decreases relative to the projector motor speed. If the tape runs faster than the film, the loop around the loop arm shortens and the arm reduces the resistance of the variable resistor. This is wired in series with the projector motor and speeds up the latter. If the film runs faster than the tape, the loop lengthens and the resistance is increased, to slow down the projector motor.

In this way the tape recorder and projector automatically remain in step. The actual linear speeds of tape and film need not be the same, as the gearing between the projector motor and the tape capstan can allow for this. (With an 8 mm. projector running at 16 f.p.s. the linear speed of the film is 2·4 inches per second, while the speed of the tape may be 3¾ or 7½ ins. per second.) The film and tape can go out of synchronism if the tape stretches or creeps (in other words slips in contact with the capstan). This can be prevented by using a perforated tape running around a sprocket instead of a smooth capstan.

The second method is the mechanical coupling of the tape and the film drives. The tape recorder may be built into the projector, with both driven by the same motor, or the tape driven by a mechanical link from the projector motor.

In an electrical coupling system the tape recorder motor feeds electrical signals into the projector which are compared with similar

signals produced by the projector motor. If the two are both running at the correct speed, the signals will be in phase; on going out of phase the speed of the one or the other is automatically adjusted.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The fourth method is a kind of electrical perforation. The tape here carries synchronizing pulses on the second track alongside the recorded sound and the pulses control the projector speed.

When projecting a film and running a tape with the synchronized sound effects, both must start at the right point in the projector and tape recorder respectively. For this purpose starting marks are made on both the film and the tape, and the two threaded up so that these marks are opposite specific index points. Then run the film—before the beginning of the show—until the first title is in the gate and stop both the projector and the tape recorder. To start the show itself simply start both together (usually by a joint switch).

To reduce the risk of synchronization errors it is best to project the film and run the tape on the same machines as were used for synchronizing the film with the tape in the first place (i.e. the same projector and the same tape recorder). Provided the same tape recorder is available for every showing, the loop synchronizing method can even be used with different projectors, where these have similar provision for the mechanical coupling between the tape recorder and the projector.

These methods are cumbersome when multi-reel films are shown, since getting the film and the tape to the correct starting points takes a little more time. However multi-reel films are usually library copies which already carry an optical or magnetic sound track.

While projecting keep monitoring the sound. If the tape and the film go out of synchronism due to the tape stretching or creeping immediate adjustment is needed. Some units have an overriding control to adjust the projector motor to bring the sound and the picture together again. L.A.M., M.K.K. and R.M.F.

Film Storage. A cool, dry storage place is the best to prevent deterioration of films. Narrow-gauge non-flammable base is the most sensitive to atmospheric conditions. Excessive dryness causes it to become brittle and shrink. Excessive damp causes mildew to attack the emulsion layer.

To counteract the possibility of shrinkage and mildewing there are humidifying solutions—a few drops on a small piece of absorbent material in the can are adequate to keep the roll of film in condition. The humidifier should not be allowed to touch the film itself and in the case of certain colour films is not recommended at all. Fortunately the climate of Great Britain is not usually of the extreme nature that makes the use of humidifiers imperative.

Applications of the Film. Since the early days when animated pictures were still a novelty surrounded by an air of magic, there has been a tremendous development and widening in the scope of the uses of cinematography. Nowadays the existence of film is taken for granted—it is part of our everyday life.

Entertainment is, of course, its main business, made up of such varied artistic offerings as the feature films, cartoons, newsreels, documentaries, and fictional films made specially for children. The commercial world also uses films for advertising; and film sequences are made for the television services where direct television is impossible or inconvenient. But 35 mm. film does not have by any means a monopoly of practicability.

Narrow-gauge films had been introduced solely to cater for amateurs and their personal pleasure. But 16 mm. was soon recognized as having great possibilities in serious work. It has obvious advantages in lightness of equipment and lower cost, and so it has been developed to satisfy the modern needs of many different fields. Good colour is so easily obtained and sound is a routine facility.

Portable equipment made 16 mm. ideal for use in schools. Education films cover a range of subjects that is literally world wide. The inclusion of these visual aids at the right places in the curriculum has proved effective in teaching. The appreciation of film is so great in some schools that the children are encouraged to make their own productions which, although fictional, are considered as part of a constructive policy towards the arts.

Eventually 8 mm. film improved sufficiently in quality to become a serious proposition for the educational and industrial applications originally reserved to 16 mm. film. The current 8 mm. sound film systems with magnetic stripe and even with optical sound tracks have opened a variety of new applications, especially where small and compact projectors make the equipment still more portable than 16 mm. machines. Thus small—and even battery driven—projectors are finding growing use as sales aids, etc. G.H.S. and J.C.

WIDE SCREEN AND THREE-DIMENSIONAL CINEMA PROJECTION

For more than half a century the cinema presented a picture of a format adopted by Lumière and Edison, having an aspect ratio of approximately 1·33 to 1. When the introduction of sound brought the musical film into popularity, it was appreciated that a wider screen would enhance the appeal of many types of scene. But it was not until the 1950's, when the powerful competition of television forced the cinema industry into devising new attractions, that these systems were commercially employed.

As a result, we see pictures on screens of all sizes, in a variety of aspect ratios. The principles adopted can be classified under four headings, as in the next section.

The terms "stereoscopic" and "three-dimensional" have been lavishly misused in reference to these systems. The true stereoscopic film enjoyed a brief period of popularity in the cinema, but did not survive. This was due to three factors; a lack of understanding by producers of the principles of stereoscopy; indifferent projection; and the dislike of audiences to wearing special viewing glasses.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Wide Screen Techniques. It is nevertheless to some extent true that a picture of increased width, enhanced by colour of the high standard that is today possible, helps to create a sensation of depth.

There are four ways of making the picture fill a wider screen: a normal picture can be enlarged to fill the width of the wider screen if some of the foreground and the top of the picture can be sacrificed; the camera can be adapted to embrace a wider field; a film wider than normal can be employed; the screen may be filled by running two or more projectors side by side.

(1) Wide screen with standard picture. The first system is the one generally referred to as Wide Screen projection. In this case the term indicates projection of a standard 35 mm. film on to a screen with an aspect ratio which is increased above the standard figure of 1·33 to 1 by reducing the height of the projector aperture, and installing a lens of shorter focal length. The top and bottom of the picture are thus masked off and wasted. Aspect ratios of 1·66, 1·75 and 1·85 are commonly used, i.e., a typical size of screen might be 16 × 28 feet, aspect ratio: 1·75.

Because of the increased magnification of the image, loss of definition inevitably occurs in projection. This is due primarily to the limited resolving power of the negative. A method designed to overcome this fault consists in substantially enlarging the area of the negative frame by running the negative horizontally in the camera and exposing an area greater than two normal frames. This enlarged image is then reduced in printing to the standard frame size so that the release prints can be shown in standard projectors.

(2) Wide screen with wide picture. This system is based on the use of an anamorphic lens on the camera which doubles the angle of view in the horizontal direction only so that the resulting image on the film is "squeezed". In projection, a similar anamorphic optical attachment "unsqueezes" the picture to fill a screen of 2·55 to 1.

WIDE SCREEN PROPORTIONS. Top: *Projection of a wide screen image on to a normal size screen wastes the top and bottom of the screen area.* Bottom: *Ideally a wider than normal screen should be used.*

In many cinemas this ratio cannot be accommodated without reducing the height of the picture—e.g., a cinema whose normal screen measures 18 × 24 feet may have to reduce the height of the picture to 15 feet in order to install a screen of 38 foot width, to accommodate a picture of this aspect ratio.

In view of the width of the screen, a special sound installation is desirable. The standard 35 mm. film gauge is modified to provide space for a number of magnetic sound tracks carrying records made by microphones spaced across the whole width of the scene. These tracks feed speakers positioned to the right, centre and left of the screen, and an effects track feeds speakers distributed around the auditorium. The audience is thus given the impression of hearing sounds coming from the actual sources on the screen.

(3) Wide screen with wide film. A number of films have been produced on film 70 mm. in width, and with an increased picture height, producing in projection an aspect ratio of 2 : 1. The film also carried six magnetic sound tracks, five feeding speakers behind the screen and the sixth the ambience speakers in the auditorium. Films made in this gauge have shown themselves capable of a standard of projection hitherto unequalled in the cinema.

(4) Wide screen with multiple pictures. In a typical multiple projection system, the taking camera has three lenses, positioned at angles of 48° with their axes crossing. These lenses expose three separate films which, although upon standard 35 mm. stock, have frames six perforations in height instead of four. The sound is recorded upon six magnetic tracks.

In projection, three projectors, two of them at an angle of 48° either side of the axis, cover a large and deeply curved screen, which may measure 50 or 60 feet in chordal width.

This type of projection is possible only in specially equipped halls.

Curved Screen. To secure adequate picture brightness with the increased screen sizes of the new projection systems, highly directional screen surfaces must be used. A more even distribution of reflected light, and hence a more even brightness of the picture as viewed from the side seats, results if the screen is slightly concave to the audience.

The radius of curvature is often made equal to the projection throw.

An audience seated close to a deeply curved picture experiences a sensation of participation referred to as "engulfment". This happens when the angle subtended by the picture to the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MULTIPLE IMAGE SYSTEM. Three projectors project three images side by side on a curved screen, with slight overlap at the edges. The three films are taken by a corresponding three-camera set-up and must remain accurately synchronized during projection. A, loudspeakers behind screen (actually there are five) and in auditorium for stereophonic sound effects. B, screen. C, optimum viewing area. D, projectors.

viewer approximates to the normal angle of view of the eye. The illusion may be further strengthened by the use of directional sound.

To enable pictures of different aspect ratios to be projected, the masking of the sides of the screen is made adjustable, generally controlled from the projection room.

360° Projection. An ingenious novelty consists in projecting pictures upon a series of screens forming a complete circle, the audience standing inside. In one system demonstrated, 11 projectors are positioned in spaces between the 11 screens, each projector throwing its picture upon a screen opposite it. The films so projected may be of different but related subjects, or may give the effect of a complete 360° angle of vision. For instance one may see a car approaching, turn to see it side view, and turn right round to see it vanishing in the distance.

Stereoscopic Projection. The above systems cannot give more than an approximation to the real sensation of depth created by true binocular viewing in which each eye sees a different picture. This requires that the subject should be photographed from two separate viewpoints, spaced $2\frac{9}{16}$ inches apart, and the resulting films must be projected on to a screen in such a way that each eye sees only the picture made through the corresponding taking camera lens. The two impressions then fuse in the brain to produce the characteristic feeling of depth.

Numerous truly stereoscopic methods have from time to time been worked out. The number of practical projection methods reduces in effect to three, and the underlying principle can be stated as follows.

We can project two images only on the screen, and use special viewing devices to separate them at the eyes; or we can dispense with viewing apparatus altogether if we accept the complexity and expense of providing multiple images and a special screen.

(1) Anaglyph method. Each pair of images is produced in complementary colours. These are superimposed by projection, and spectacles also in complementary colours are used to separate the images. This method can of course only be used for monochrome, and apparatus used to be sold for converting a viewing cabinet into a projector for use with this system. The method was devised by d'Almeida in 1858.

(2) Polarization method. This was the system previously employed in the cinema. The right and left eye images are printed upon separate films, and projected through lenses fitted with polarizing screens. The images are polarized in planes at right angles, and are superimposed on the screen. The viewers are provided with spectacles of similar polarizing material, which separates the images at the eyes,

THREE DIMENSIONAL PROJECTION. Two projectors project matched stereo films (or stereo images on one film projected with a beam-splitter twin-lens projector) on to the screen through polarizing filters. The audience have to wear polarizing spectacles with the viewing filters for the left and right eyes oriented with their planes of polarization parallel to the corresponding left and right hand projection filters.

Circular polarization is claimed to possess advantages over the usual plane polarization method. All polarization methods of projection have the disadvantage that considerable loss of light takes place at the polarizing screens.

(3) Special screens. In the special screen systems, the screen is constructed in such a way that the viewers see the separate images of the stereoscopic pair without spectacles.

Raster screens consist of an arrangement of vertical wires interposed between the screen surface and the audience. Two types have been the subject of experiment: one in which the wires from the surface of a truncated cone, within which the projection screen is situated. There are also patented screens in which the projection surface is composed of vertical lenticular prisms, or of spherical lenticular elements graduated in size.

These methods make possible the viewing of stereoscopic films without spectacles or other optical aids, but the apparatus is expensive, and the stereoscopic picture can only be seen from certain positions in the auditorium.

It has been proposed to rotate, or to impart horizontal reciprocating motion to the raster screen to reduce the effect of the vertical wires.

In all systems the projector axes must be kept parallel to avoid geometrical distortion, so the images are superimposed by offset of the lenses. Depolarization of the images in polarized light systems may occur at wide viewing angles, resulting in a double image.

In a more advanced system in development, the polarizing materials are embodied in the actual film coating, one image being carried on either side of a single film.

A different principle necessitates a large convex lens or concave mirror in place of the screen. If at any pair of conjugate points are situated respectively the stereo pair and the eyes of the observer, each eye will see its appropriate image without the need for viewing devices. For obvious reasons the system is limited to a very small number of observers. R.H.C.

Amateur Wide Screen Projection. For amateur use with narrow-gauge film only the wide screen techniques with standard or wide picture are of practical significance. With existing 8 mm. and 16 mm. equipment usually only the squeezing of the image with an anamorphic lens is feasible, followed by "unsqueezing" with a similar attachment on the projector.

Wide-screen projection with a standard picture is also feasible if the film is shot in such a way in the first place, that any loss of image area at the top and bottom of the frame can be allowed for. At least one 8 mm. camera has an adjustable film gate by which the image area may be reduced in height to give a greater aspect ratio. In this case no masking of the projector gate is necessary, provided that the spaces between the frames on the film are opaque. The frame intervals must naturally remain constant.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

For projection of such images of reduced height, a wide-angle lens is needed to obtain a screen image of normal height and extended width. The degree of magnification of the image on the screen is then greater than normal, and may therefore show up unsharpness, grain, etc.

A number of ways of modifying the layout of images on narrow-gauge films have been proposed for obtaining pictures of greater aspect ratio. An obvious one would be to modify a normal 8 mm. camera by enlarging the film gate so that the film is exposed across its full width simultaneously instead of down one half only. This therefore would give a 3 : 1 aspect ratio—extreme wide screen—with a frame size of around 10 × 3·3 mm. The camera has to be fitted with a wide-angle lens (i.e. of wide coverage rather than shorter focal length) mounted so as to cover the full film width. The film is projected in a 16 mm. projector, with the gate suitably masked down and the transport system modified to advance the film by an 8 mm. instead of a 16 mm. frame interval at a time. Modifications of this kind have been carried out by enthusiastic amateurs.

The double 8 mm. film used in such a set up must of course not be slit during processing.

A more practical method, sponsored commercially for a short time, is a modified 9·5 mm. film with two perforations between the frames instead of one. The film runs through the camera horizontally and is exposed only along one half of the width (like double 8 mm.). This gives an image of half the area of the normal 9·5 mm. frame, but an aspect ratio of about 1·6. After exposure of the other side of the film and processing, the film is slit in double-8 mm. fashion.

Suggestions have been made that this idea could be adapted to ordinary 8 mm. film, doubling the standard frame area to yield a wider picture through running the film horizontally through the camera. The resulting aspect ratio would be around 1·66. A significant point is that with this system (running the film horizontally through a camera and projector) the wide screen effect is not obtained at the expense of image quality. In a roundabout way this is the nearest equivalent to wide screen projection with a wide film in commercial motion picture theatres. L.A.M.

PROJECTION PRINCIPLES

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

When several observers wish to view a positive at the same time, an enlarged image of it may be projected by a suitable optical system on to a viewing screen.

OPTICAL FACTORS

A number of optical factors determine the quality of the image, its apparent brightness and its size.

Image Quality. The quality of the image is affected by aberrations in the optical system. These aberrations are reduced by using optical components specially designed for the purpose.

Then the quantity of light passing through the system must be sufficient to provide an adequate level of illumination on the screen. This is a matter of photometry and it dictates a great part of the design of the optical equipment.

A few of the more important photometric principles and definitions may be summarized before considering any particular projection system.

When a lens system, fulfilling the optical sine condition and having no absorption losses, forms an image of an object on a screen, the illumination is BA/T^2 lumens per square foot (i.e., foot-candles), where B is the intrinsic brightness of the object in candles per square foot, A is the effective area of the lens aperture, and T is the throw or distance from lens to screen.

If the object is a perfectly diffusing surface with 100 per cent reflectivity and is illuminated by one foot-candle, its intrinsic brightness is $1/\pi$ candles per square foot, or one foot-lambert. Similarly, if the viewing screen is a perfect diffuse reflector (or transmitter) and is illuminated by one foot-candle, its apparent brightness is one foot-lambert. Such a screen is said to have a "gain" of unity in all directions.

If the object is a transparency illuminated by a well designed aberration-free condenser system with no absorption losses, the apparent intrinsic brightness of its clear parts, when viewed from the projection lens, is the same as that of the light source. Similarly, the aperture of the projection lens when viewed from the screen appears to have the same brightness and it can in fact be considered as a source of that brightness and of that size.

Image Brightness. The theoretical illumination on the screen, ignoring light lost by absorption and reflection, depends on three factors: it is directly proportional to the intrinsic brightness of the object (and to the brightness of the source in the case of transparencies) and to the effective area of the projection lens aperture, and it is inversely proportional to the square of the throw.

Before we can determine the relative aperture that is required in the optical system, the type of light source, its size and how it is to illuminate the object, we must have some idea of the screen brightness to be aimed at. The following table gives a very rough indication of what is ideal for various applications.

SCREEN BRIGHTNESS

Location	*Screen Brightness Foot-lamberts*
Cinemas	9–15
Schools (partial black-out)	8–12
Schools (complete black-out)	4– 8
Houses (daylight on average curtains) ...	2– 5
Houses (complete black-out)	1– 2

No screen will reflect or transmit all the light incident upon it and if it is perfectly diffusing its gain in all directions will be less than unity. These figures must therefore be divided by the gain of the particular screen to be used before we can decide the necessary illumination in foot-candles.

So, for a school with complete black-out where a screen brightness of 8 foot-lamberts is wanted with a screen of gain = $\frac{3}{4}$, the actual illumination figure would be $(8 \times 4)/3 = 10\frac{2}{3}$ foot-candles.

There are special directional screens which can appear to be much brighter in a particular direction than any diffuse surface.

In cinematography allowance has to be made for the fact that the illumination is intermittent and the projector while running produces only about half the illumination it does while stationary.

Image Size. The size of a screen image depends on three factors: the size of the object being projected, the focal length of the projection lens, and the distance between the projection lens and the screen.

When using a standard projector with a fixed object (i.e., slide or cine frame) size and one projection lens the size of the screen image for a particular screen distance is given by:

$$I = \frac{O\,(U - F)}{F}$$

where U is the distance of the projection lens from the screen, F its focal length, O the width of the object being projected, and I the width of the screen image.

For example, suppose 24 × 36 mm. transparencies are projected by a 4 ins. lens on to a screen 8 feet from the lens. 36 mm. is approximately 1·4 ins. so the screen width is:

$$I = \frac{1{\cdot}4\,(96 - 4)}{4} = \frac{128{\cdot}8}{4} = 32\tfrac{1}{4}\text{ ins.}$$

The screen distance required to yield a given screen dimension from one object size and one

projection lens can be obtained by rearranging the above equation into the form

$$U = \frac{F(I + O)}{O}$$

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

With a 4 ins. projection lens a screen image width of 4 feet is obtained when the screen distance

$$U = \frac{4\,(48 - 1{\cdot}4)}{1{\cdot}4} = \frac{186{\cdot}4}{1{\cdot}4} = 133 \text{ ins.}$$

The focal length of a projection lens to suit any combination of object size, screen size and screen distance is obtained from the equation:

$$F = \frac{U\,O}{I + O}$$

In the previous examples the projection lens focal length required to yield a 4 feet wide screen picture 8 feet from the lens is:

$$F = \frac{96 \times 1{\cdot}4}{48 + 1{\cdot}4} = \frac{134{\cdot}4}{49{\cdot}4} = 2\tfrac{3}{4} \text{ ins.}$$

The values of F obtained in this way may correspond to angular covering powers beyond the capabilities of the available projection lenses and the screen width may have to be reduced or the distance increased to reach a more usable focal length. G.H.C.

Zoom Lenses. A projection lens of variable focal length greatly simplifies the problems of setting up the projector to obtain either a given screen image size or a given projection distance. Usually zoom projection lenses have a focal length ratio of 1 : 1½ to 1 : 3. With an average ratio of 1 : 2, the available latitude works out as follows.

For 24 × 36 mm. transparencies, a projection lens with a focal length variable from 3¼ to 6½ ins. and the screen again 8 feet from the lens gives for the shortest focal length:

$$I = \frac{1{\cdot}4\,(96 - 3{\cdot}25)}{3{\cdot}25} = 40 \text{ ins.}$$

and for the longest focal length:

$$I = \frac{1{\cdot}4\,(96 - 6{\cdot}5)}{6{\cdot}5} = 19\tfrac{1}{4} \text{ ins.}$$

So the screen width is variable from 19¼ to 40 ins.

Equally the zoom lens enables a fixed screen image size to be obtained from a range of projection distances. Using the second of the above examples, for a screen image width of 4 feet and a projection lens variable from 3¼ to 6½ ins. the shortest screen distance is

$$U = \frac{3{\cdot}25\,(48 - 1{\cdot}4)}{1{\cdot}4} = \text{approx. } 108 \text{ ins.}$$

while the longest distance is

$$U = \frac{6{\cdot}5\,(48 - 1{\cdot}4)}{1{\cdot}4} = \text{approx. } 217 \text{ ins.}$$

The available range of projection distances is directly proportional to the zooming range of the lens.

The greater the zooming range, the greater obviously the possible combinations of screen size and screen distance that can be used in the equation

$$F = \frac{U\,O}{I + O}$$

and as long as the resulting value for F falls within the focal length range of the lens, the combination is feasible for a projection set-up with that lens. Nor need the lens be changed when using different combinations of U and I (the object size for a given projector is usually constant).

In practice the even greater value of a zoom projection lens is that the projector can be set up at a required distance without too much concern for the screen image size. This is then adjusted independently by varying the focal length of the lens so that the picture fills the screen.

Zoom projection lenses are predominantly used in the home projection of cine films and still transparencies. Projection lenses of longer focal length are not normally available as zoom lenses. Such long focus lenses are used mainly for projecting in larger halls and auditoriums where both the projection distance and the screen size are more or less fixed and no adaptation to varying conditions is necessary. The only exception is educational cine film projection where a projector may have to be set up in classrooms and other locations with conditions varying from one place to the next.

Image Aspect. Most of the time comparatively little attention is—or indeed can be—paid to the viewing angle of the screen image relative to the audience. It is generally recommended that viewers should not be so near the screen as to get a distorted impression of the picture, nor so far that smaller details become unrecognizable. The usually accepted ratio of nearest and farthest distances is around 1 : 8 and this is the space within which the audience can be accommodated.

For ideal viewing conditions the range is very much reduced. "Ideal" in this context implies a viewing distance where the screen image is seen in the same perspective as the original view. This depends on the focal length of the camera lens used to take the picture or film and on the magnification of the screen image. The product of the two is the ideal viewing distance. Thus for a 24 × 36 mm. transparency taken with a 2-ins. (50 mm.) camera lens and magnified to a screen image width of 4 feet (magnification of approximately 34×) the ideal viewing distance would be about 58 ins. or a little under 6 feet.

As it is rarely practical to concentrate the audience into such a restricted distance range from the screen, the consideration of ideal viewing distance has to be largely ignored. This is helped in practice by the fact that the eye adapts itself in the darkened room to a large number of distortion factors (colour, brightness, etc.) including perspective. Further, as a

proportion of still and even more cine views are shot with long-focus lenses the average viewing distance shifts somewhat backwards to take in a deeper audience.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Wide-angle Projection. A special case of the deliberate choice of image aspect relative to the observer is the projection of wide-angle shots (taken with a short focus lens in the camera) on a large screen for viewing at comparatively close distances. As a result the audience sees a much wider view than the eye can take in simultaneously, yielding an impression of increased reality and depth.

This is partly due to the fact that an observer in the audience can let his eyes roam over the screen in much the same way as he would look all round the original scene. The visual viewing angle then becomes more nearly that of the natural angle of observation (rather than optical angle of view) of the eye. Though the latter is around 140°, an image angle of even half this value is already far more impressive than the more usual viewing angle of 20° to 40°.

With a 24 × 36 mm. transparency taken with a 35 mm. ($1\frac{3}{8}$ ins.) camera lens and the observer 6 feet from the screen, the screen image width would have to be around $6\frac{1}{4}$ feet for this wide-angle effect. For greater viewing distances the screen width must be extended in proportion.

Such a set-up raises two practical issues. First the comparatively restricted ideal viewing distance also limits the size of the audience for such a show. Secondly the image usually also has to be projected by a short focus projection lens which must have an adequate angular covering power. This enables the projector to be set up not too far behind the audience, though that is a practical convenience for projection in smallish rooms. In principle it is the image magnification on the screen, relative to the viewing distance, which counts; the same effect can be achieved by a projection lens of more normal focal length with the projector set up rather further behind the audience.

Such a wide-angle projection arrangement is generally practical only for slides—mainly because the angle of view of wide-angle cine lenses (at any rate for amateur use) corresponds to the angle of a normal still camera lens (rarely exceeding 45° to 50°). Wider angles are then only obtainable with special optical attachments such as anamorphotic lenses. L.A.M.

PROJECTION SYSTEMS

Most classifications of projection systems divide them into two broad groups: projection of opaque originals by reflected light (episcopic projection) and showing transparent originals by transmitted light (diascopic projection). Projectors are accordingly designed for either system; some models provide for both.

Episcopic Projection. The simplest form of projector from the theoretical point of view is the episcope in which the light reflected from a brilliantly illuminated opaque object is focused by a lens system to form an image on a screen.

As the light is reflected by the object in all directions, only a small percentage falls on the lens and passes through to form the image. Because the amount of useful light available is so small, it is not possible to have a large bright screen image.

The screen illumination is given by the equation $E = BA/T^2$ where E is the illumination on the screen, B is the brightness of the perfectly white parts of the object, A is the area of the projection lens aperture and T is the throw.

An illumination on the object of 10,000 foot-candles is possible if it is near a 2,000 candle-power lamp reinforced by mirror surfaces, i.e., B is $10{,}000\pi$. With an episcope giving a magnification of 20 with an 8 ins. f 4 lens, the throw

STILL PROJECTOR SYSTEMS. Left: *Episcope. No direct light reaches the photograph but only light reflected from the walls of the lamp house.* A, *screen.* B, *plane mirror.* C, *lens.* D, *lamp house.* E, *filament lamp.* F, *photograph.* Right: *Film strip and slide projector.* G, *lamp reflector.* H, *lamp.* I, *double condenser.* J, *transparency.* K, *projector lens.* L, *screen.*

is 168 ins. and the area of the lens is 3·14 square ins. E is therefore

$$\frac{10{,}000 \times 3{\cdot}14}{3{\cdot}14 \times 168 \times 168} = {\cdot}35 \text{ foot-candles.}$$

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

In practice E would be less than this because the object and the projection lens absorb light and with such a low screen illumination the episcope would have to be used in a completely darkened room. The screen illumination can be improved by using a lens with a wider aperture, being satisfied with a smaller image or increasing the brightness of the object by using a more powerful lamp.

If the projector is on the same side of the screen as the viewer, the image formed by the lens system is, of course, laterally inverted (the right and left sides are interchanged). This is undesirable, particularly if the subject includes writing or print, so the projected beam of light must be reflected from a mirror placed immediately in front of the projection lens to invert it back again to normal. With back projection, no lateral inversion takes place and the mirror is not required.

There is a very similar arrangement for projecting transparencies in which a well illuminated diffusing screen is placed behind the object, making a combination that can be considered as self-luminous. Here again it is difficult to obtain sufficient light on the screen since the amount of illumination diffusely transmitted is not greatly different from that diffusely reflected by a white object under the episcope.

The lateral inversion of a transparency can be overcome by turning it around in the slide holder.

Diascopes. Another form of projection system suitable for transparencies uses a condensing system to form an image of the light source in the pupil of the projection lens whilst the cone of light forming that image passes through the transparency.

If the condensing system is free from aberration, all light rays from the light source passing through the transparency enter the projection lens aperture. So, when looked at from this aperture, all clear parts of the transparency appear equally bright. Provided the size of the image of the light source is slightly greater than the aperture of the projection lens (i.e., the lens is completely "flashed"), the size of the source and its magnification are on the whole immaterial.

Since current consumption and heat emission increase with increasing source size, it is usual to choose the greatest magnification and smallest source that the aberrations of the condenser system permit.

In calculating how much light is projected on to the screen, there is one big difference between episcopic and diascopic projection. Since we can use the light emitted from all the surfaces of the light source in the episcope, we want to know its total candle-power.

With the diascope, however, the condenser system and projection lens will determine how much of the source surface is usefully employed and in this case we want to know its intrinsic brightness in the direction of projection, i.e., how bright the illuminated transparency looks when viewed from the projection lens.

Since the light sources specially designed for this work are relatively small and capable of considerable light output, their brightnesses are more conveniently expressed in candles per square centimetre.

As an example, for an 8 ins. *f* 4 lens working at a magnification 20, and a transparency illuminated by a light source with a brightness of 750 candles per square centimetre, the illumination on the screen, at points corresponding to the perfectly clear parts of the object, is (750 × 3 14)/(168 × 168) lumens/sq. cm. or

$$\frac{750 \times 3{\cdot}14 \times 929}{168 \times 168} = 77 \text{ lumens/sq. foot (foot-candles)}$$

A comparison with the very similar episcope example, giving a screen brightness of ·35 foot-candles, shows that the diascope makes a very much better projector.

This intensity of illumination is unnecessarily high for ordinary projection even when an allowance is made for light absorption and scatter in the optical system and for poor screen material. It would be reduced in practice by using a lens of smaller aperture, by increasing the magnification or by using a lamp of lower intrinsic brightness.

The tungsten filament lamps which are almost always used in projection of this sort give off a great deal of heat and if the transparency is in the form of film strip a heat absorbing glass filter will be necessary. This will reduce the amount of light reaching the screen by some 15 per cent.

Epidiascope. Some manufacturers incorporate episcopic and diascopic principles in one instrument which is known as an epidiascope. Its essential features are an enclosed space containing the illuminant and alternative means of illuminating either a transparency mounted at the front or a solid object at the bottom. There must be a lens at the end of a tube in front of the transparency for diascopic projection; and a lens and mirror at the top for episcopic projection.

Back Projection. Another arrangement consists of projecting the image from the rear on to a transulcent screen. While this can be done with any projector, it is usually a feature of compact cine and still projectors used for educational and demonstration purposes. There the screen forms an integral part of the projector housing. This screen is generally fairly small and the image is intended for daylight viewing. The actual brightness in terms of light output utilized is lower than for a reflection screen, but where

AMATEUR CINE PROJECTION SCREEN SIZES AND IMAGE DISTANCES. Top: 16 mm. (silent and sound) and 8 mm. narrow gauge film. Bottom: 9·5 mm. silent and 9·5 mm. sound film. The height of the screen image in the case of 8 and 16 mm. film as well as 9·5 mm. silent is three-quarters of the width; with 9·5 mm. sound film it is slightly more than three-quarters. All screen image sizes are based on the projector gate aperture, and not on the actual frame size on the film; the latter is slightly larger.

the image is small the amount of light concentrated on the screen is sufficient to give an image plainly visible in daylight.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Any back-projection arrangement is a compromise between image brightness and evenness of illumination. The more translucent the screen is, the brighter the picture but the greater the risk of a "hot spot" in the middle of the field with a noticeable falling off of illumination towards the edges.

A screen that provides reasonably even illumination therefore has to absorb considerably more light than a surface screen to be viewed by reflection.

For daylight projection the surface characteristics of the screen from the viewing side are also important. A normal translucent screen will reflect any light falling on it, and extraneous light therefore is liable to degrade the image. Special back projection screens exist with highly directional reflection characteristics, where any reflected light is seen only from the direction of the light source. Such a screen is thus selective in favour of transmitted light and against reflected light.

When the image is projected on to a screen from the back, it appears reversed left-to-right from the front. Most back projection set-ups therefore use a surface silvered mirror or a reflecting prism to obtain a right-reading image from the front of a screen when the film or transparency is loaded into the projector in the normal way.

This mirror system also makes the back projection set-up more compact, since normally the projector-to-screen distance behind the screen would have to be the same as when the projector is set up in front with a reflection screen.

Cinema Projection. In the third type of projection system used for large screen cinematography, the source is imaged on the transparency instead of the projection lens.

This method is chosen because the film frame is usually smaller than the projection lens aperture and permits the use of a smaller source. That keeps current consumption and heat emission within practical limits.

If the source were imaged on the back of the lens, the necessary condenser conjugates would be very short and the light source would be brought very near to the film where it would be in the way of the mechanism and where its heat could not be tolerated.

Because filament lamps do not give the necessary uniformly bright light source, cinema projectors use either the carbon arc or the high pressure vapour lamps. These are sufficiently uniform for the purpose, and give the much higher brightnesses essential for large screens.

Modern narrow gauge amateur projectors also use a similar system in conjunction with a low-voltage lamp (which has a very small and compact filament) with built-in reflector. The latter is often a blown-out part of the bulb itself, internally silvered and shaped in such a way that all the light is focused on the image plane.

LIGHTING SYSTEMS

The light system in a projector must give even illumination, it must avoid light losses, and it must not transmit too much heat to the slide.

The Light Source. Tungsten filament lamps are generally used in miniature film strip, transparency or positive projectors. They have a high intrinsic brightness and for practical reasons they are mostly lamps of low voltage taking a large amount of current, with the filament wound in tight coils set close together.

The lamp relies on the high operating temperature of the tungsten and emits more energy

CINE PROJECTOR SYSTEMS. Top: Commercial cinema projector utilizing an arc lamp and concave reflector. The optical principal of the integral reflector lamp, used without a condenser on amateur cine projectors, is similar. Bottom: Filament lamp and relay condenser system. The first condenser forms an image of the source in the plane of the second condenser, while the latter forms an image of the first condenser on the film. The third condenser forms an image of the second one in the plane of the lens. A, reflector. B, light source. C, film. D, lens. E, screen, F, G and H, condensers.

in the form of heat than light, so the lamp used is always the smallest that the condenser system permits. Smaller lamps are also more economical.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Because of the heat emitted by these lamps, the lamphouse must be well ventilated and often cooled by an electric fan to prevent the glass from softening.

Tungsten melts at 3655° K. and at this temperature has a brightness of about 6,000 candles/sq. cm. The filament in projector type lamps operates between 2,900° K. and 3,400° K. yielding brightnesses of the metal between 1,000 and 3,000 candles/sq. cm. The effective brightness of any useful area of the source includes, of course, non-radiating space due to the turns in the coils and the spacing between them, and an average brightness of about 1,500 candles/sq. cm. is approximately the best that can be hoped for theoretically.

If this type of source is placed at the centre of curvature of a concave mirror, an image of the coils can be formed in the non-radiating spaces, thus increasing the average brightness. The improvement varies with different lamps, but seldom exceeds 50 per cent.

The more recent electric discharge lamp consists of an arc between tungsten electrodes contained in mercury vapour. It is capable of a very high light output without a corresponding increase in heat emission. A high pressure mercury vapour lamp can produce several times the screen illumination given by a tungsten filament lamp of the same wattage with far less heat

Such lamps are more robust and last longer than tungsten filament lamps.

The ordinary mercury vapour discharge lamp is very suitable for monochrome projection but it does not give a perfectly true rendering of colour because its emission of green and blue light is greater than the red emission. Specially made lamps are used for projecting colours. These carry mercury vapour at a higher pressure and also contain other elements such as cadmium so that the light emitted approximates white light.

The xenon arc has the discharge taking place in an atmosphere of xenon gas at high pressure. This type of lamp is progressively replacing carbon arc lamps in professional cinema projectors and is even made in small versions for narrow-gauge projectors. The advantage of the xenon arc is the colour quality of the light (which approaches daylight), and the high light efficiency with considerably simpler operating gear.

The concentrated arc lamp is another light source that is used for very small projectors. It has fixed electrodes sealed in an argon-filled bulb and the light is emitted from a thin film of molten zirconium and the neighbouring vapour. The source itself is quite small—ranging from ·003 in. diameter in a 2 watt lamp to ·10 in. in a 300 watt lamp.

A special discharge lamp developed for cinema projectors is a pulse-arc, a concentrated gas arc with an intermittent light of 72 flashes per second. This is used with shutter-less projectors, the pulsing light taking the place of the continuous light cut off periodically by the projector shutter. This gives greater light efficiency, as no light is wasted during the dark periods.

The lamp itself is only just over 3 ins. long, the brightness is equivalent to a 60-amp. high-intensity arc.

The following table gives an indication of the approximate brightnesses of various types of light source.

PROJECTION LIGHT SOURCES

Light source	*Volts*	*Watts*	*Brightness candles/ sq. cm.*
Tungsten filament	50	250	1,000

The Condenser System. The optical arrangement of lenses and/or mirrors which illuminates the object cannot affect the definition of the final image to any appreciable extent, but it can and very often does affect the variation of illumination over the field.

A very common form of condenser lens system consists of two plano convex lenses with their vertices almost in contact, and in this case the focal length and *f*-number of each is twice that of the whole. An aperture of about *f*1·5 is the limit for any single element of a system having all surfaces spherical.

Excessive spherical aberration, which varies as the square of the lens diameter, may evidence itself as wide dark annular rings on the screen.

These occur when all the rays from a zone of the transparency do not get through the projection lens, and its aperture will not appear to be filled when viewed from the corresponding image point at the screen.

If the aberrations of a condenser system cannot be accepted, the focal length—and hence the *f*-number—must be increased by using a larger source and a smaller magnification, or alternatively it must be replaced by another system containing more elements with shallower surfaces, or one containing aspheric surfaces.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Another optical system uses what is known as a relay condenser. In this the first component forms an image of the source on a second component which in turn forms an image of the first on the film. At the same time a third component very close to the film forms an image of the second, and therefore of the source, in the aperture of the projection lens.

This type of condenser system provides very even illumination, and is particularly efficient if one or two of the elements have aspheric surfaces.

In the third type of projection a uniform source is imaged on the object. In this case the image-forming cone of light should flush the projection lens aperture, i.e., the condenser and lens apertures have to subtend the same angle at the object.

A very common arrangement uses an ellipsoidal mirror with the source at one focus and its image at the other. A relay condenser for this type of projection consists of only two components (although each component may have more than one element). Both components combine to form an image of the source on the object, whilst the second forms an image of the first in the projection lens aperture. This second image must flash the lens aperture.

In the integral reflector lamp the ellipsoidal mirror is the specially shaped and silvered rear portion of the glass bulb itself. The front of the bulb is also blown out to a spherical shape and silvered, leaving only an opening for the concentrated light beam. The result is a sufficiently intense and focused beam to require no condenser system at all. The film is at the second focus of the ellipsoidal reflector. This arrangement is particularly compact, but is so far available only for 8 mm. and 16 mm. cine projectors.

Light Transmission. The light lost at the various glass-to-air surfaces and absorbed by the thickness of the glass reduces the illumination on the screen. The loss at a glass-to-air surface is 4 or 5 per cent of the light reaching it from preceding surfaces according to the type of glass, and the absorption in the glass itself is, very approximately, 2 per cent per inch. So even with a system of very thin components having fourteen glass-to-air surfaces, only about 55 per cent of the light reaches the screen.

Coating or "blooming" lens surfaces reduces the loss to about 1 per cent at each surface. A thin system of fourteen bloomed surfaces may transmit as much as 85 per cent of the available light.

The coating consists of a film, 4-millionths of an inch thick, of a transparent material having a refractive index as near as possible equal to the square root of the index of the glass. It is usually applied by evaporating magnesium fluoride on to the glass in a vacuum.

This light loss applies equally to the light passing through the condenser system. Hence projectors relying on integral reflector lamps without condensers can, in certain circumstances, utilize more of the light output of the lamp.

Heat Transmission. The heat emitted by very bright tungsten filaments is sufficient to ruin the object placed in an episcope or diascope unless special precautions are taken. Episcopes usually have forced air cooling, and most diascopes include a heat absorbing filter made from special glass. The energy absorbed by the filter is conducted away by air currents.

Although heat filtering glass has a lower coefficient of expansion than usual, it will crack if the illumination on it is not uniform and for this reason the whole surface, including the extreme edges, must be exposed to the radiation.

When it is impossible to obtain uniform heat over a large filter it is divided into several strips about 1 in. wide mounted edge to edge.

A polished sheet of this glass 3 mm. thick absorbs about 91 per cent of the heat energy and about 13 per cent of visible light.

All elements of a condensing system which lie close to a source of great heat, or to an image of it, are made from heat resisting glass or fused quartz.

A further method of reducing the heat reaching the film or transparency being projected involves the use of diathermic lamp reflectors. These are special glass reflectors coated with a dichroic layer which reflects up to 90 per cent of the visible wavelengths of the light, but transmits 80 per cent or more of the long wave infra-red radiation. In this way virtually the only heat reaching the film or slide in the picture gate is the direct radiation from the filament itself.

That is effectively less than half the heat radiated in a conventional lighting system with a fully reflecting reflector.

Diathermic reflectors may be separate and mounted behind the lamp, but a number of modern projection lamps have integral or proximity reflectors of the diathermic type built in. G.H.C. (L.A.M.)

PROJECTION PRINTING. Any method of printing in which the image is projected on to the sensitized material by an optical system—e.g., an enlarger. Projection printing is normally employed to produce images of different size from the original, but may also serve for same-size reproduction.

PROJECTOR (CINE)

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

It is in the cine projector that the motion picture film creates its illusion of movement. The projector has three functions; to hold the long strip of individual images exposed in the camera (the cine film) to feed these images through the projection system at a standard speed, keeping each image in position for an instant; and to project an enlarged picture on to the screen.

The main components of the projector are thus the intermittent film transport; the shutter, the illuminating optics (lamp and means for directing the light on to the film gate), the projection lens, and the film containers (reels) and means for guiding the film past the point where it is projected. In a sound projector there are also the sound unit where the sound recording is picked up, the reproducing amplifier and the loudspeaker.

Sizes. Amateur cine projectors are available for the three main film gauges; 8 mm., 16 mm., and 9·5 mm. Motion picture theatre projectors project 35 mm. or 60 mm. film, and there are semi-professional models—mainly for educational and industrial use—for 16 mm. and occasionally even for 8 mm. film.

Multi-gauge projectors also exist, projecting two or even three narrow-gauge film sizes. Changing over from one gauge to another there involves interchanging the transport elements (claws and sprockets) to adapt the machine to the different perforation intervals, the film channels and the spools and spindles. Multi-gauge models are rather rare; few people make films of more than one gauge and it is easier to achieve maximum precision in a projector designed for one film gauge.

A TYPICAL SILENT PROJECTOR. The components and controls are: A, lamp; B, condenser; C, mirror; D, shutter; E, motor and cooling fan; F, feed spool; G, sprockets; H, roller guides; I, lens; J, film gate; K, claw mechanism; L, take-up spool.

Projector Types. Cine projectors can be grouped according to the film gauge and specifications.

Silent 8 mm. projectors usually have a single projection speed of 16 frames per second, lamp power up to 500 watts (or a low voltage lamp of 50 or 100 watts), and—on modern models—automatic film threading. More advanced projectors may have two running speeds, forward and reverse, still picture device, etc.

8 mm. sound projectors for striped film usually have two speeds of 16 (or 18) and 24 frames per second, and have a sound-head and amplifier unit built on or are provided with a separate unit for direct linking with the projector. Sound projectors using the tape coupling system may have a tape coupler built in or be intercombined with a tape recorder deck.

There are two types of 8 mm. projector (in silent and sound versions) for classical 8 mm. and for Super-8 mm. films. The films differ in the image format and perforations, certain universal 8 mm. machines take both film types.

16 mm. silent projectors are comparatively rare. They usually have a running speed of 16 frames per second, sometimes reverse running and usually a still picture device, and lamps of 500 to 1,000 watts (mains voltage) or low voltage lamps of 150 watts.

16 mm. sound projectors nearly always have speeds of 16 and 24 frames per second, and may have provision for playing back optical or magnetic (striped film) sound tracks or both; sometimes they also have provision for recording a magnetic sound track. On compact models the amplifier and speaker are built into the projector housing. Versions for educational projection in large halls may have separate speakers. Professional 16 mm. sound projectors for cinema use often employ arc lamps.

Mostly 9·5 mm. projectors follow the general specifications for 8 or 16 mm. machines according to complexity. 9·5 mm. sound projectors may screen films with optical or magnetic (stripe) sound tracks.

Special projectors, particularly for 8 mm. film, include compact models with built-in rear projection screen, cassette loading, etc.

FILM TRANSPORT

In the projector the film runs from a take-up spool or reel over a transport sprocket, through the film track and past the film gate (the opening through which the film is illuminated), over another sprocket and—in the case of a silent projector—on to the take-up spool or reel. The

MOTION PICTURE THEATRE PROJECTOR. The most advanced models of this kind can handle 35 and 70 mm. film and sometimes also 16 mm. film with accessory attachments. A, film feed spool in fireproof drum. B, upper fireproof channel C, lamphouse (usually for carbon or xenon arc lamps). D, film indicator window on lower drum containing take-up spool. E, magnetic sound head. F, gate. G, lens. H, optical sound head. J. drive motor.

first sprocket pulls the film smoothly off the feed spool and the second sprocket (sometimes the other side of the same sprocket) passes the film—again at a uniform rate—on to the take-up spool. The latter is usually driven through a friction clutch which enables the take-up spool to reel up just as much film as the second sprocket feeds through.

The Loop. While the sprockets move the film smoothly, the latter passes through the film gate in jerks. This is because the intermittent film movement must keep each individual film frame stationary in the gate for an instant, then quickly pull the film down to hold the next frame for an instant, and so on. To absorb this jerky movement and to prevent it from straining the film, there is a free loop of film above and below the gate. In threading the projector it is important to maintain these loops; if through a fault in the mechanism or damage to the film perforations a loop (usually the bottom one) gets too short, the direct pull on the film through the gate may cause damage.

Intermittent Movement. The commonest means of moving the film intermittently through the gate in a narrow-gauge projector is the film claw. This engages the film perforation, pulls the film down through one frame interval, and disengages to return to its starting point for the next transport cycle. Usually the pull-down time is between one-sixth and one-quarter of the complete transport cycle; for the rest of the time the film is stationary in the gate.

There are many variations of the claw movement, and various means of coupling it to the transport motor to achieve an ideal moving cycle (i.e. where the claw moves as far as possible at right angles to its pull-down direction during engagement and disengagement). The movement may have a double or a triple claw, to pull down a film even with occasional damage to perforation holes.

Heavy duty 16 mm. and practically all 35 mm. projectors use a Maltese cross movement which intermittently advances the film through a special sprocket. This puts less strain and wear on the film perforation, but is a more bulky and more expensive mechanism. Dog or beater movements, acting on the film loop have also been used.

The Shutter. While the film is moved in the gate, a shutter interrupts the light beam to prevent blurring of the picture on the screen. The shutter consists of a rotating blade shaped somewhat like a fan. This not only stops light from reaching the screen while the film moves from one frame to the next, but also serves to eliminate flicker in the picture.

Flicker. It was discovered quite early in cinematography that while a picture change occurring sixteen times a second was sufficient to give an illusion of movement, the audience was aware of light flicker. Tests showed that to obtain an illusion of continuous flicker-free illumination it was necessary to interrupt the light beam forty-eight times per second. For this reason the silent film projection shutter has three blades and three openings. The shutter rotates once for every frame so that it

PROJECTOR INTERMITTENTS. Top left: Claw movement with double claw. The arrowed figure traces the path of the claw; BB is the extent of the film movement. Top right: Dog or beater movement. As the beater acts on the film loop, BB is only half the length. Bottom: Maltese cross system.

produced forty-eight interruptions per second at a projection frequency of sixteen frames per second.

When sound-on-film was introduced, the film had to be run at a faster speed so that the higher sound frequencies could be satisfactorily recorded and reproduced. The picture frequency was increased to twenty-four frames per second and at that speed the projection shutter needs only two blades and two openings to provide the necessary forty-eight interruptions.

The Motor. The sprockets, intermittent movement, shutter and take-up spool are all driven by one projector motor. Usually this runs at a fixed speed to pull the film through at 16 frames per second in a silent projector or 24 f.p.s. in a sound machine. Amateur sound projectors often provide a choice of both speeds to permit the showing of silent and sound films.

A few projectors also incorporate a special slow speed of 5 or 6 frames per second, to create slow-motion effects on the screen with films shot at a normal speed. Owing to the extreme slowing down the image motion tends to be slightly jerky, but this slow-motion projection is valuable for movement analysis, etc. Some specialized projectors for this purpose even have a range of analysis speeds from 1 to 8 frames per second, so that the film can virtually be examined frame by frame.

At such slow motion speed the problem of flicker arises again. Where the shutter is directly geared to the film movement, slow-motion projectors may have a system of splitting up the shutter blades so that the 3-blade shutter for instance becomes a 9-blade one the moment the machine is switched to projection at 5 f.p.s. This gives 45 interruptions per second, near enough to the normally stipulated 48. At still slower projection speed the pull-down time becomes so short in comparison with the period the film is stationary in the gate, that the resulting movement blur on the screen would not be noticeable anyway. So the shutter movement is there disengaged from the film transport, and the shutter continues to rotate at a constant speed to give 48 interruptions per second, irrespective of the film transport rate. (The shutter is still needed for projection at the normal speeds.)

Some amateur projectors have a reversing switch for running the film backwards, to cause amusing effects or enable a scene to be quickly repeated. Frequently a still picture device is also fitted, which holds the frame in the projector indefinitely. In this case an additional heat filter is automatically switched into the optical path to prevent damage to the film. Neither of these features is normally fitted to 35 mm. motion picture projectors.

Spools and Rewinding. The maximum spool size, and hence the film capacity, varies with the different gauges, but not very greatly with different projector models. Usually 8 mm. machines take 400-feet spools, which gives a screening time of just over half an hour at 16 f.p.s. or little over 20 minutes at 24 f.p.s. Some 8 mm. projectors hold up to 800-feet spools.

Most present-day 16 mm. projectors are sound models and have spool capacity of 1,600 or even 2,000 feet. This provides up to one hour of continuous screening. The capacity of 9·5 mm. projectors also goes up to 1,600 feet. Cinema projectors for 35 mm. usually take 2,000 feet spools. Since this only gives about 20 minutes of screening time at sound-film speed, more frequent change-over is necessary during the cinema performance. This is usually achieved with two projectors and may be controlled automatically or semi-automatically.

Generally amateur projectors incorporate a motorized rewind to wind the film from the take-up spool back to the feed spool for the next performance. For this purpose the take-up and feed spools are interchanged on the spool arms, and the film led directly from the full spool on the feed spindle to the empty one. High speed rewinding however carries some risk of film damage; for that reason it is usually better to rewind the film on a separate rewinding mechanism where the speed is under control; this also permits checking the film for faults during rewinding.
